ESHG Plenary Lectures

PL1.1
Integrating chromosome structure and function during X-chromosome inactivation

E. Heard;
Institut Curie, Unité de Génétique et Biologie du Devéloppement, CNRS UMR3215, INSERM U934, Paris, France.

Using the mammalian process of X-chromosome inactivation as a model, we are interested in understanding how the differential treatment of identical DNA sequences in the same nucleus can be achieved during early mammalian development. The establishment of X inactivation involves a complex locus, the Xic, which produces the non-coding Xist RNA that is the trigger for chromosome-wide silencing. X inactivation is also accompanied by numerous epigenetic modifications that ensure stability and heritability of the inactive state. By investigating the regulatory landscape of the Xic locus using chromosome-conformation capture technologies and super-resolution microscopy, we recently uncovered a new level of chromosome folding into topologically associating chromosome domains (TADs), each spanning hundreds of kilobases (Nora et al, 2012). TAD organization was shown to be highly conserved, genome-wide phenomenon in mammals (Dixon et al, 2012). Sequences within TADs tend to interact more frequently and may thus provide a scaffold for privileged interactions between genes and their regulatory sequences. We demonstrated that within the Xic, TADs enable the precise coordination of gene expression dynamics during early differentiation and also underlie the partitioning of epigenomic landscapes, such as histone modifications. In our recent work we have further explored the functional relevance of TADs using physical modeling, as well as genetic engineering approaches at the *Xic* locus. We have also investigated the extent to which TAD organization is predictive of coordinated gene expression and epigenomic dynamics at the genome-wide scale.

PL1.2
Signaling transcription factors explode dogmas in brain development and disease

A. Prochiantz[1,2];
[1]Paris, France, [2]Collège de France, Paris, France.

The concept of homeoprotein transduction, first proposed in 1991, is now well established in several biological systems. Because homeoprotein signaling is active in plants and animals it is proposed that it has predated the separation between animals and plants and is thus very ancient. This may explain why the basic phenomenon of homeoprotein transduction is so minimalist, requiring no specific receptors or specialized transduction pathways. Indeed complexity has been added in the course of evolution and the conservation of homeoprotein transduction can be discussed in the context of its synergy with bona fide signaling mechanism that may have added robustness to this primitive cell communication device. The same synergy possibly explains why homeoprotein signaling is important both in embryonic development and in adult functions fulfilled by signaling entities (e.g. growth factors) themselves active throughout development and in the adult. Several functions have been identified, including morphogenesis, axon and cell guidance and plasticity of the cerebral cortex. In addition some homeoproteins have been used as therapeutic proteins in animal models of human diseases including glaucoma and Parkison disease. Although it is clear that many questions are still in want of answers, it appears that the sequences responsible both for secretion and internalization are in the DNA-binding domain and very highly conserved among most homeoproteins. On this basis, it can be proposed that this signaling pathway is likely to imply as many as 200 proteins that participate in a myriad of developmental and physiological pathways.

PL1.3
Life-threatening infectious diseases of childhood: single-gene inborn errors of immunity?

J. Casanova;
New York, NY, United States.

"The hypothesis that inborn errors of immunity underlie infectious diseases is gaining experimental support. However, the apparent modes of inheritance of predisposition or resistance differ considerably between diseases and between studies. A coherent genetic architecture of infectious diseases is lacking. We suggest here that life-threatening infectious diseases in childhood, occurring in the course of primary infection, result mostly from individually rare but collectively diverse single-gene variations of variable clinical penetrance, whereas the genetic component of predisposition to secondary or reactivation infections in adults is more complex. This model is consistent with (i) the high incidence of most infectious diseases in early childhood, followed by a steady decline, (ii) theoretical modeling of the impact of monogenic or polygenic predisposition on the incidence distribution of infectious diseases before reproductive age, (iii) available molecular evidence from both monogenic and complex genetics of infectious diseases in children and adults, (iv) current knowledge of immunity to primary and secondary or latent infections, (v) the state of the art in the clinical genetics of non-infectious pediatric and adult diseases, and (vi) evolutionary data for the genes underlying single-gene and complex disease risk. With the recent advent of new-generation deep resequencing, this model of single-gene variations underlying severe pediatric infectious diseases is experimentally testable."

PL2.1
Mutations of TCF12, encoding a basic-helix-loop-helix partner of TWIST1, are a frequent cause of coronal craniosynostosis

Craniosynostosis is the premature fusion of cranial sutures. It is a heterogeneous disorder with a prevalence of approximately 1 in 2,200 and in ~22% of cases, a specific genetic cause can be identified. This includes mutations of TWIST1, which encodes a class II basic helix-loop-helix (bHLH) transcription factor, causing Saethre-Chotzen syndrome, typically associated with coronal synostosis. We exome sequenced 7 patients with bilateral coronal synostosis, identifying loss-of-function mutations in TCF12 in 3 cases. TCF12 encodes a class I E-protein that heterodimerizes with class II bHLH proteins such as TWIST1. Further sequencing of individuals with craniosynostosis identified a total of 38 heterozygous TCF12 mutations in 347 unrelated samples. Furthermore, 14 cases arose de novo. The mutations predominantly occurred in patients with coronal synostosis, accounting for 32% and 10% of subjects with bilateral and unilateral pathology, respectively. Comparing surgical trajectory of TCF12-mutation positive patients with other genotypes reveals a favourable post-operative course. 14% had associated learning disability. A significant level of non-penetrance of craniofacial features (53%) was found in 34 mutation-positive individuals from 23 families also tested. Relevant cephalometric measurements were normal and there was no evidence of somatic mosaicism. TCF12 lies in a region of strong linkage disequilibrium and initial haplotype investigation demonstrates phe-

notypic variability may be due to genotypes that protect from or predispose to craniosynostosis. TCF12 and TWIST1 act synergistically in a transactivation assay, and mice doubly heterozygous for loss-of-function mutations have severe coronal synostosis, demonstrating that normal coronal suture development critically depends on heterodimer dosage.

Katsanis*[2], *A. Groffen*[1], *E. Sistermans*[1];
[1]*VU medical Center, Amsterdam, Netherlands,* [2]*Duke University Medical Center, Durham, NC, United States,* [3]*Signature Genomic Laboratories, Spokane, WA, United States,* [4]*Harvard University, Boston, MA, United States,* [5]*Cambridge University Hospital, Cambridge, United Kingdom,* [6]*University of Toronto, Toronto, ON, Canada,* [7]*University hospital Ghent, Ghent, Belgium,* [8]*Nationwide Children's Hospital, Columbus, OH, United States,* [9]*Antwerp University, Antwerpen, Belgium,* [10]*University of Washington, Seattle, WA, United States.*

Translocations involving 7q21.22 have been associated with autism and intellectual disability (ID). Discordant evidence has suggested that these clinical phenotypes might be driven by a number of genes (*AUTS2, WBSCR17, CALN1*). Here, we examined whether *AUTS2* disruptions are causal for neurocognitive defects.

An international cohort of ~50,000 patients and 16,000 controls was examined for CNVs in *AUTS2* by array CGH and we performed detailed phenotypic analyses. 5'RACE experiments were performed to test for alternative transcripts in human brain. A zebrafish knock down model was generated to test the potential of different *AUTS2* splice isoforms to induce some of the anatomical phenotypes seen in patients.

We found 44 *AUTS2* deletions. Microdeletions disrupting the coding sequence were causal to a complex syndromic ID/autism phenotype including short stature, microcephaly, cerebral palsy and distinct facial dysmorphisms. The exonic *AUTS2* deletions occur with a frequency comparable to *NSD1* deletions causing Sotos syndrome. We also discovered a novel, highly conserved, C-terminal *AUTS2* isoform in human brain. Clinical and functional studies showed this isoform to be a key contributor to the human phenotype because (a) patients with C-terminal deletions exhibited significantly more severe and pleiotropic aspects of *AUTS2* syndrome, and (b) the significant microcephaly and craniofacial defects seen in *auts2* knockdown zebrafish embryos were rescued by this C-terminal isoform.

We identified a hitherto unappreciated syndromic phenotype caused by deletions in *AUTS2,* required for both brain and craniofacial development. The C-terminal portion of the gene contributes significantly to the phenotype, demonstrating how transcriptional complexity can underpin human pathology.

PL2.3

MED4: a suicide gene to explain low penetrance in retinoblastoma patients

C. Dehainault[1], *A. Garancher*[2], *L. Castéra*[1], *I. Aerts*[3], *F. Doz*[3], *L. Lumbroso*[4], *R. Montes-de-Oca*[5], *G. Almouzni*[5], *D. Stoppa-Lyonnet*[1,6], *C. Pouponnot*[2], *M. Gauthier-Villars*[1], ***C. Houdayer***[1,6];
[1]*Institut Curie, service de génétique, Paris, France,* [2]*Institut Curie, INSERM U1021, Orsay, France,* [3]*Institut Curie, service de pédiatrie, Paris, France,* [4]*Institut Curie, service d'ophtalmologie, Paris, France,* [5]*Institut Curie, UMR 218 CNRS, Paris, France,* [6]*université Paris Descartes, Sorbonne Paris Cité, Paris, France.*

Monoallelic germline loss of function mutations in the *RB1* gene predispose to a high risk of bilateral retinoblastoma, following loss of heterozygosity of the second *RB1* allele in the tumor. Surprisingly enough, complete germline *RB1* deletions are associated with low or no tumoral risk . This low penetrance might be explained by the homozygous contiguous deletion of an unknown gene adjacent to *RB1*, essential for survival when LOH occurs and without which the *RB1* -/- cell cannot survive.

To test this hypothesis, we mapped an entire germline *RB1* deletion interval in an unaffected carrier and extended this analysis to a series of tumors carrying two full *RB1* deletions. By comparing the mapped germline and somatic intervals that included or excluded the gene, respectively, and by eliminating genes with poor expression in retinoblastoma cells, we selected two gene candidates : *NUDT15* and *MED4*. We tested our 'suicide gene' hypothesis by downregulating *MED4* and *NUDT15* in two retinoblastoma cell lines. Briefly, we ruled out *NUDT15* as a candidate gene. In contrast, reduced *MED4* expression decreased cell proliferation and anchorage independent growth and induced apoptosis as measured by FACS analysis using caspase 3 as a marker. Together our results suggest that retinoblastoma *RB1* -/- cells cannot bear the loss of *MED4* expression, thereby explain the low penetrance in patients with deleted *RB1*. These new results may offer novel perspectives for therapeutic intervention adapted to patients with cancers where *RB1* is inactivated.

The orchestration of proliferation and differentiation of neuronal stem cells prior to their radial migration to the cerebral cortex is central to brain development in humans. Periventricular neuronal heterotopia (PH), the mislocalisation of grey matter centrally within the brain, can indicate a failure of neuronal progenitors to negotiate some aspect of this developmental process. Using combinations of autozygosity mapping and exome sequencing, bi-allelic mutations in genes encoding a pair of giant cadherin proteins that operate as a receptor-ligand pair are shown to lead to van Maldergem syndrome (VMS; MIM 601390) a recessive multiple malformation syndrome in humans characterized by intellectual disability, craniofacial, auditory, renal, skeletal and limb malformations in addition to a partially penetrant PH phenotype. In 6 unrelated families with the disorder both truncating and missense mutations were characterized, indicating a loss of function mechanism in the genesis of VMS. To understand the mechanism behind compromised cadherin receptor-ligand engagement in the genesis of impaired neuronal migration in the mammalian brain, we employed in utero shRNA directed knockdown of both genes in mouse embryos. A reduction in expression of both genes resulted in an increase in neuroprogenitor cell number combined with a block in differentiation of neuronal precursors, resulting in the heterotopic accumulation of cells in the subcortex. These findings, which are reminiscent of the human phenotype, underscore the existence of links between neuroepithelial layer integrity and the control of proliferation and differentiation of neuronal precursors during human cortical development.

BMN111, a CNP analogue, potential novel investigational therapy for achondroplasia

L. Legeai-Mallet[1], *N. Kaci*[1], *J. Peng*[2], *C. Benoist-Lasselin*[1], *T. Oppeneer*[2], *L. Tsuruda*[2], *C. A. O' Neill*[2], *F. Di Rocco*[1], *A. Munnich*[1], *F. Lorget*[2];
[1]*INSERM U781-Institut Imagine, Paris, France,* [2]*BioMarin, Novato, CA, United States.*

Achondroplasia (ACH), the most common form of dwarfism, is an inherited autosomal dominant chondrodysplasia caused by a gain of function mutation in the fibroblast growth factor receptor 3 (FGFR3). Among the possible targets to antagonize FGFR3 signaling, we chose the C-type natriuretic peptide (CNP) strategy. CNP acts as a key regulator of longitudinal bone growth by down-regulating the MAPK pathway. The constitutive activation of this same pathway, due to a FGFR3 gain-of-function mutation, is the cause for impaired bone growth in ACH patients.
We characterized the pharmacological activity of BMN 111, a CNP analogue peptide that has an extended plasma half-life compared to that of the native CNP due to its resistance to neutral endopeptidase degradation. In ACH growth plate chondrocytes, we demonstrated that BMN 111 decreased MAPK pathway activation. In Fgfr3Y367C/+ mice mimicking ACH, daily subcutaneous administration of BMN 111 led to the attenuation of the dwarfism phenotype. We observed a significant increase in the axial and appendicular skeleton length with improvements in ACH related clinical features including flattening of the skull, increase in the size of the paws and digits, straightening of the tibias and femurs. A rescue of the height and architecture of the different zones of the growth plate was also observed. BMN 111 treatment led to the largest improvement in skeletal parameters observed to date in an Fgfr3 mouse model.
Our results support further development of BMN 111 for the treatment for ACH.

Monocytes are a subset of white blood cells belonging to the innate immune system. They can differentiate into macrophages and dendritic cells to elicit key functions (phagocytosis and antigen presentation, respectively) at sites of inflammation. Genome-wide association studies (GWAS) have identified several loci but, in most cases, the specific causal variants and their relative impact on the immune system remain unknown.
Here, we measured circulating monocyte counts in 5,894 individuals enrolled in the SardiNIA project. Samples were genotyped using four different Illumina Beadchip arrays: OmniExpress, Cardio-MetaboChip, ImmunoChip and ExomeChip. To increase the genomic resolution, we imputed ~17 Million variants from a reference panel of 1,488 unrelated Sardinian samples sequenced at an average of 4x coverage. We searched for additive effects using a mixed association model accounting for population structure and samples' relatedness, and we observed 5 significantly associated loci (pvalue<5x10-8), of which 3 are novel. Among the two loci known to influence monocyte counts, we replicated the signal at the ITGA4 gene (r2=0.98 with previously reported SNP); moreover, fine mapping suggests a novel variant near LPAR1, which likely regulates the expression levels of the gene (r2=0.53 with a reported eQTL). Notably, the novel loci include strong biological candidates, such as a variant highly correlated (r2=0.97) with a missense mutation located in the gene coding for suppressor of activated monocytes with critical role in inflammation and tumorigenesis.
Our results suggest that sequencing-based GWAS contribute to a better understanding of the genetic basis of monocyte counts regulation and function.

PL4.1
Mendel Lecture: Rett syndrome and *MECP2* Disorders: From the Clinic to Genes and Neurobiology

H. Zoghbi;
Investigator Howard Hughes Medical Institute Professor, Baylor College of Medicine and Director, Jan and Dan Duncan Neurological Research Institute at Texas Children's Hospital, Houston, TX, United States.

Rett Syndrome, a postnatal neurological disorder that causes a broad range of severe neurological and behavioral disabilities, is fascinating in that its symptoms appear after a period of normal development and point to disturbances in most brain cells and regions. The quest for the gene revealed that the disease is caused by mutations in MECP2. The path from gene discovery to therapy, however, is not a straightforward one and requires deep understanding of pathogenic mechanisms and key molecular and anatomical determinants of various symptoms and pathologies. We have used genetic, behavioral, physiological and molecular approaches to interrogate the pathogenesis of Rett and MECP2 disorders.Recent discoveries suggest that MeCP2 is critical for many neuronal functions, especially for the ability of neurons to respond to change. Moreover, the findings reveal functions of the protein that were not suspected previously.

H. Zoghbi: None.

PL5.1
ESHG Award Lecture

F. Mitelman;
Lund, Sweden.

Immense amounts of data on neoplasia-associated chromosomal aberrations have been collected during the last three decades. Chromosome abnormalities have been described in more than 60 000 human neoplasms, and a substantial number of the cytogenetic changes have now also been characterized at the molecular genetic level. The most important fact that has emerged from the cytogenetic studies is the realization that every tumor type that has been studied in a sufficient number to permit conclusions may be subdivided on the basis of characteristic, often specific, and sometimes even pathognomonic, rearrangements. An increasing number of the recurrent aberrations, in particular balanced changes, are with remarkable specificity associated with distinctive morphological and/or clinical disease characteristics. The identification of these recurrent changes has several important implications. First, cytogenetics has become an increasingly important tool in the clinical management of cancer patients to help establish a correct diagnosis, to predict prognosis, and to select the most appropriate treatment. Second, the cytogenetic information has provided invaluable help to identify genes of importance in the carcinogenic process by focusing the attention to chromosomal sites that may harbor genes which when rearranged lead to neoplasia. So far, all balanced structural rearrangements

that have been characterized at the molecular level have been found to exert their action through one of two alternative mechanisms: deregulation of a seemingly normal gene in one of the breakpoints, or the creation of a hybrid gene through fusion of parts of two genes, one in each breakpoint. Presently, almost 3,000 recurrent balanced chromosomal rearrangements and more than 1,500 gene fusions have been reported, each of potential pathogenetic and/or clinical significance. It is reasonable to assume that the achievements obtained to date, albeit impressive, probably only represent the tip of the iceberg.

Concurrent Symposia

S01.1
Evolutionary pressures and gene expression regulation

Y. Gilad;
The University of Chicago, Department of Human Genetics, Chicago, IL, United States.

Changes in gene regulation are thought to play an important role in adaptation and speciation, notably in primates. However, the extent to which changes in different regulatory mechanisms underlie gene expression evolution is not yet known. To address this gap, we comparatively characterized gene expression (using RNA sequencing) and genetic and epigenetic regulatory mechanisms in humans, chimpanzees, and rhesus macaques, using LCLs from 8 individuals from each species. Specifically, we used ChIP-seq to obtain genome-wide profiles of H3K4me3, H3K4me1, H3K27me3 and H3K27ac histone modifications, as well as binding of RNA polymerase II. We also collected DNaseI-sequencing from the same LCLs, and by using the CENTIPEDE algorithm we measured the strength of transcription factor binding for over 200 transcription factors in all three species. These data allowed us to identify both conserved and species-specific enhancer and repressor regulatory elements, as well as characterize similarities and differences across species in transcription factor binding to these regulatory elements. We found that that transcription factor binding and histone modifications in more than 67% of regulatory elements in putative promoter regions is conserved across the three species. In turn, by considering sequence conservation at genomic locations that showed differences in regulatory mechanisms across species we were able to better understand the extent to which changes in transcription factor binding are due to either cis- or trans- differences across species. Finally, we analyzed correlations between inter-species differences in the genetic and epigenetic regulatory mechanisms and variation in gene expression levels across species using a system of logistic regression models. Assuming that these correlations do imply a causal regulatory relationship, we estimate that up to 50% of inter-species gene expression differences can be accounted for by corresponding changes in transcription factor binding and/or the presence of histone modification marks.

The vast majority of disease-associated variants lie outside protein-coding regions, suggesting that variation in regulatory regions may play a major role in disease predisposition. We mapped differences in transcripton factor binding and chromatin states using six histone modifications, cohesin, Pol2 and CTCF in lymphoblastoid lines from 10-19 individuals of diverse ancestry. We find extensive signal variation in regulatory regions as well as switches of chromatin state across individuals, most frequently between active and repressed states. Enhancer activity is particularly diverse among individuals, and is strikingly divergent across populations despite a lack of similar structure in gene expression. Population specific enhancer activity often correlates with genetic divergence and is associated with signals of positive selection. Consistently, transcription factor binding and chromatin marks show strong inheritance in trios. To understand how gene regulation corrlates with protein levels, we also measured protein levels in LCL lines of 90 individual, We found that protein levels are also heritable and the approximately one half of the loci that control protein levels are independent of those that affect gene

expression Overall, our results provide fundamental insights into molecular differences in humans and how they are genetics controlled.

S02.1

The search for bone and joint genes, and what to do with them?

***A. G. Uitterlinden**[1,2,3];*

[1]Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands, [2]Department of Clinical Chemistry , Erasmus MC, Rotterdam, Netherlands, [3]Departments of Epidemiology, Erasmus MC, Rotterdam, Netherlands.

Height, osteoporosis (OP) and osteoarthritis (OA) have strong genetic influences and efforts try to identify the causal genes. Knowledge of these gene variants can help in understanding biology of the disease process and benefit development of interventions, but also have potential for diagnostics. Genome-Wide Association studies (GWAS) builds upon (1) human genetic variation, (2) genotyping technology, (3) bio-banks, and (4) collaboration among researchers in consortia. For height this is the GIANT consortium, for osteoporosis GEFOS/GENOMOS, and for osteoarthritis TREAT-OA.
GWAS has proven to be widely successful and for height, OP, OA, and Paget's Disease several GWAS have been published. For example, 80 loci have been identified for bone mineral density (BMD), ~600 loci for height, and several loci for Paget's and OA. Please note that a) GWAS identifies DNA variants rather then genes, and b) the effects per variant are generally modest, e.g., with Odds Ratios ranging from 1.1 -1.7, and explained variance of combined common variants, e.g., for height being 25% and for BMD being 3-7 %. While dozens of new loci have been discovered in GWAS, translation takes more time because a) discoveries are recent, b) there are many to choose from, and c) the conservative nature of "non-hypothesis-free" scientists.Together with studies on rare genetic syndromes, the GWAS approach clarifies the genetic architecture of the skeleton and bone and joint disease. GWAS based on SNP arrays are assessing only a small part, i.e., 0.2%, of the base pairs constituting the human genome. Next Generation Sequencing technology and exome arrys now allows to asses all coding parts of the genome (~5% of bp) and even the majority of base pairs by full-genome sequencing (~95% of bp). These approaches are now underway in Mendelian and complex disease, and for the latter again involve association approaches in large consortia.

A.G. Uitterlinden: None.

S02.2

Inflammatory bowel disease: From genes to clinical impact?

***C. A. Anderson**;*

The Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

163 independent genomic regions have now been associated with inflammatory bowel disease (IBD), an immune-mediated disease that affects the gastrointestinal tract. I will highlight a series of analyses that, when applied across a large number of disease associated loci for a given trait, allow additional insights to be drawn regarding disease relevant cell types, pathways and evolutionary selective pressures. I will also discuss on-going projects within the International IBD Genetics Consortium to identify genetic loci associated with clinically relevant disease subphenotypes such as disease location and severity. I will finish by describing the identification of a non-coding polymorphism in FOXO3 that is significantly correlated with disease severity in IBD and other TNF-alpha driven diseases such as rheumatoid arthritis and malaria infection. I will show that this locus regulates monocyte production of TNFα and IL-10 through control of TGFβ1 production. This work highlights a pathway that could, through improved patient stratification or targeting with novel agents, contribute to the development of personalised medicine in TNFα-driven diseases.

S03.1

Lynch syndrome as a model of mutations and epimutations in cancer

***P. Peltomäki**;*

University of Helsinki, Helsinki, Finland.

The DNA mismatch repair (MMR) system is crucial for cancer avoidance through the correction of replication errors, DNA damage surveillance, and other functions. Failure to properly accomplish these functions may promote cancer development. It is therefore not surprising that inherited defects in the MMR system, MLH1, MSH2, MSH6, and PMS2 genes, underlie one of the most prevalent cancer syndromes in man, Lynch syndrome (LS), previously known as hereditary nonpolyposis colorectal cancer (HNPCC). LS is estimated to account for 5% of all colorectal cancers in the population and possibly a similar share of endometrial, ovarian, and other cancers. LS not only serves as a model for cancers arising through MMR defects and microsatellite instability, which concerns 10 - 25% of all colorectal, endometrial, and other cancers, but also highlights the significance of the epigenetic component in cancer development.
Knudson's hypothesis postulates that tumor suppressor gene inactivation requires two hits, the first of which may occur either in somatic cells, giving rise to sporadic cancer, or in the germline, giving rise to hereditary cancer. The second hit is always somatic. Cumulative evidence suggests that, besides genetic mutations, either hit may be epigenetic. Increased methylation of selected tumor suppressor gene promoters is an acquired property of many tumors developing in LS, and the patterns in part mirror changes seen in the corresponding sporadic cancers[1]. Hypomethylation of LINE-1 is often less prominent in LS tumors, in accordance with their near-diploid chromosome content[2]. Like genetic instability phenotypes, epigenetic phenotypes may be associated with a preferential inactivation or activation of certain growth-regulatory genes and pathways and thereby influence prognosis and response to therapy. Importantly, inactivation of the susceptibility genes MLH1 and MSH2 by epigenetic mechanisms may occur already in the germline. Constitutional epimutations may explain around 10% of LS-suspected families which lack MLH1 or MSH2 protein expression in tumor tissue and show no genetic mutations in MMR genes in the germline[3].
Knowledge of genetic and epigenetic alterations associated with cancer susceptibility and tumor development provides the basis for improved diagnostics, prevention and therapy in the respective cancers.

S03.2

Epigenetic Programming of the Cancer Phenotype

***J. Issa**;*

Fels Institute, Temple University, Philadelphia, PA, United States.

The epigenome is reset during embryogenesis and matures around the end of development. Large scale genomic studies have now shown considerable proliferation dependent epigenome changes in aging cells (DNA methylation instability, chromatin instability). Comparison of rodent, primate and human aging shows that DNA methylation instability is conserved, depends primarily on chronologic age, and can be predicted to a certain degree by local genomic features (e.g. retrotransposons). It can therefore be argued that this epigenomic instability is a necessary result of the evolution of complex genomes that lack reprogramming capabilities in adult cells. Epigenetic instability creates gene expression variation in aging tissues that serve as an enabler of Darwinian evolution at the tissue level. Selective pressures result in cells with unique epigenetic programs that lead to diseases such as cancer or atherosclerosis. Importantly, epigenetic variation can be modulated by exposures (inflammation and perhaps diet), providing a mechanistic link between lifestyle and disease. In turn, epigenetic reprogramming could be useful for prevention and treatment of age-related pathology. In leukemias, reprogramming by DNA methylation inhibitors has gained acceptance as effective therapy for myeloid leukemias, and drugs for other epigenetic targets are rapidly proceeding towards clinical trials.

S04.1
The role of microglia in synaptogenesis
C. Gross;
Monterotondo, Italy.

Microglia are phagocytic cells that infiltrate the brain during development and play a role in the elimination of synapses during brain maturation. Changes in microglia morphology and gene expression have been associated with autism. However, it remains unknown whether these changes are a primary cause or a secondary consequence of neuronal deficits associated with the disorder. Here we tested whether a primary deficit in microglia was sufficient to induce autism-related behavioral and functional connectivity deficits. Mice lacking the microglia chemokine receptor Cx3cr1 showed a transient reduction of microglia in the brain during the early postnatal period and a consequent deficit in synaptic pruning. Deficient synaptic pruning was associated with a failure to strengthen excitatory synaptic transmission, decreased functional connectivity across brain regions, deficits in social interaction, and increased repetitive behavior, all hallmarks of autism. These findings open the possibility that deficits in microglia function could contribute to key features of autism.

S04.2
The role of glia in neurodegenerative diseases
D. W. Cleveland;
Ludwig Institute, Univ. of California at San Diego, La Jolla, CA, United States.

The great biologists of the 19th century, especially Virchow and Bernard, established the pivotal idea that individual cells function autonomously, while being part of the whole organism. Since then many the major neurodegenerative diseases have traditionally been considered mechanistically cell autonomous, meaning that damage within a selective population of affected neurons alone suffices to produce disease. Most of the genes whose mutation is now known to cause the major neurodegenerative diseases are widely or ubiquitously expressed, however, including superoxide dismutase (SOD1) whose mutation causes an inherited form of the fatal, adult motor neuron disease ALS. Modeling in mice has demonstrated that disease mechanism is through an acquired toxicity unrelated to dismutase activity. Selective gene excision has demonstrated that toxicity is non-cell autonomous, with mutant SOD1 within motor neurons and oligodendrocytes driving disease onset, while damage within neighboring astrocytes and microglia accelerates disease progression. Non-cell autonomy is a general feature of human neurodegenerative disease, including Parkinson's and frontal temporal dementia, where disease has been demonstrated to spread from cell to cell in a prion-like manner, and in Huntington's disease (HD), an inherited disease caused by tri-nucleotide expansion.
An approach to therapy is suppression of disease causing genes following infusion of DNA antisense oligonucleotides (ASOs) to direct RNase H-dependent destruction of the target mRNA widely within the nervous system. Such an approach slows disease progression in inherited examples of ALS-like disease in rodents. Moreover, infusion of ASOs targeting huntingtin mRNA effectively lowers huntingtin levels in the striatum and cortex, the primary brain targets of HD pathology. Transient infusion into already symptomatic HD mouse models mediates a sustained reversal of disease phenotype that persists for much longer than the huntingtin knockdown. These findings establish a therapeutic strategy for sustained HD disease reversal from a "Huntingtin holiday" produced by transient ASO therapy.

S04.3
Molecular genetics of axon degeneration
*J. Gilley[1], L. Conforti[2], R. Adalbert[1], S. Milde[1], **M. Coleman**[1];*
[1]The Babraham Institute, Cambridge, United Kingdom, [2]University of Nottingham, Nottingham, United Kingdom.

The Slow Wallerian degeneration protein (WldS) is an aberrant protein that arose in mice and protects distal axons after injury. Ectopic expression of WldS exerts the same protective effect in transgenic rats, flies and zebrafish, and in transfected human neurons. It also preserves axons in some neurodegenerative disease models, including inherited models of peripheral neuropathy and motor neuron disease.
Structure-function studies of WldS show that its intrinsic NAD synthesizing (Nmnat) activity is critical for axon survival. Of the three normal mammalian Nmnat isoforms, only Nmnat2 has been confirmed to be in axons. Nmnat2 is essential for axon survival and has a short half-life, so axons require its constant replenishment by axonal transport. When delivery of Nmnat2 is prevented by nerve injury, or by knockdown or knockout of Nmnat2, axons degenerate or fail to grow. WldS can rescue them by replacing the Nmnat enzyme activity and does so for a prolonged period as it has a much longer half-life.
Nmnat2 lies at the head of a signaling pathway regulating axon degeneration, and this pathway implicates several genes in axon survival. Nmnat2 degradation is at least partially controlled by ubiquitination, and the Drosophila ubiquitin ligase Highwire and its mammalian orthologue Phr1 are candidates for this. Downstream of Nmnat2, we identify a rise in the metabolic intermediate NMN as a key event, and inhibition of Nampt, the enzyme catalyzing NMN synthesis, preserves injured axons. Further downstream Sarm1, a Toll-like receptor adapter, is necessary for axons to degenerate in both Drosophila and mice. Evidence of further genes regulating axon survival is emerging from screening in Drosophila and there is a strong likelihood that these functions will be conserved in mammals.
Identification of further axon survival proteins, and their organization into a pathway, should facilitate rational decisions as to the most promising targets for axon degeneration disorders.

S05.2
Diagnostic exome sequencing in genetically heterogeneous disease
L. E. L. M. Vissers;
Dept of Human Genetics, Radboud University Medical Centre, Nijmegen, Netherlands.

Exome sequencing is of great use in a diagnostic setting to establish a genetic diagnosis, especially for those diseases where the current diagnostic yield is low due to the genetic heterogeneity of the disease. The analysis and interpretation of exome data in a diagnostic setting is however challenging, and requires methods for quality control, minimizing the possibility of incidental findings but simultaneously allowing for easy and flexible interpretation of exome sequencing data for diagnosing patients.
During this presentation I will discuss results that were obtained in our diagnostic lab by analyzing patients with intellectual disability using family-based sequencing. Additionally, I will show data obtained in patients with *e.g.* blindness, deafness, ataxias and metabolic disorders that were analyzed using "gene packages", an approach in which exome sequencing is followed by a targeted analysis of known disease genes. To further expand the possibilities of diagnostic exome sequencing for mutation detection we have recently validated automatic CNV detection on exome data and compared its performance to that of high resolution genomic microarrays. This analysis shows that exome sequencing can reliably detect the large majority of pathogenic *de novo* CNVs. Together, these data provide further arguments to use exome sequencing as a first tier test for genetically heterogeneous diseases.

L.E.L.M. Vissers: None.

S05.3

Prioritizing disease-causing variation by genomic data fusion

Y. Moreau;
University of Leuven, Leuven, Belgium.

NGS has rapidly increased our ability to discover the cause of many previously unresolved rare monogenic disorders by sequencing rare exomic variation. However, after standard filtering against nonsynonymous single nucleotide variants (nSNVs) and loss-of-function mutations that are not present in healthy populations or unaffected samples, many potential candidate mutations are often retained and we need predictive methods to prioritize variants for further validation. Several computational methods have been proposed that take into account biochemical, evolutionary and structural properties of mutations to assess their potential deleteriousness. However, most of these methods suffer from high false positive rates when predicting the impact of rare nSNVs. A plausible explanation for this poor performance is that many of these predicted variants are mildly deleterious, but in no way specific to the disease of interest. We therefore propose a genomic data fusion methodology that integrates multiple strategies to detect deleteriousness of mutations and prioritizes them in a phenotype-specific manner. A key innovation is that we incorporate into our strategy a computational method for gene prioritization, which scores mutated genes based on their similarity to known disease genes by fusing heterogeneous genomic information. We also integrate haploinsufficiency prediction scores that predict the probability that the function of a gene is affected if present in a functionally haploid state. To integrate or fuse these data sources, we develop a machine-learning model using the Human Genome Mutation Database (HGMD) of human disease-causing mutations compared to three control sets: common polymorphisms and two independent sets of rare variation. Benchmarking on HGMD demonstrates that this integrative phenotype-specific variant prioritization significantly outperforms state-of-the-art predictors, such as SIFT or PolyPhen-2.

S06.1

Identification of the gene for mixed polyposis syndrome: the end of a 50-year journey

I. Tomlinson;
Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom.

Hereditary mixed polyposis syndrome (HMPS) was first described in the early 1960s in a Jewish family from St Mark's Hospital, London. Affected individuals develop unusual, large-bowel polyps of several different types and individual polyps can have more than one morphology. Many individuals have colorectal cancer and disease dominantly inherited. After identifying several more HMPS families. all of Ashkenazi origin, we mapped the HMPS gene to a shared haplotype of ~2Mb on chr15q13.3. Sequencing found no protein-coding mutations, but we eventually found a constitutional 40kb copy number gain upstream of Gremlin 1 that is unique to HMPS patients. The HMPS duplication affects a genomic control region, leading to massive over-expression of Gremlin and relocation of its expression from the colorectal mesenchyme to the epithelium. The HMPS mutation provides a very rare example of a Mendelian condition caused by a non-coding duplication that has profound effects on gene expression. We have recently shown that HMPS tumours probably initiate with *KRAS* or *BRAF* mutation that does not cause senescence. *APC* mutations then follow, leading to dysplasia and cancer. A *Vill-Grem1* mouse recapitulates the principal aspects of the human disease.

S06.2

The role of IL7R in childhood T-cell acute lymphoblastic leukemia

J. T. Barata;
Instituto de Medicina Molecular, Lisboa, Portugal.

T-cell acute lymphoblastic leukemia (T-ALL) is an aggressive subtype of the most frequent childhood cancer. Interleukin 7 (IL-7), a cytokine produced in the bone marrow, thymus and other organs, is absolutely essential for T-cell development. However, there is evidence that IL-7 may also partake in leukemia development. We showed that IL-7 activates PI3K/Akt/mTOR signaling pathway, thereby mediating viability, cell cycle progression and growth of human T-ALL cells *in vitro* and that IL-7 can accelerate human T-ALL *in vivo*. The evidence that IL-7 can impact on leukemia maintenance drove us to evaluate whether genetic alterations involving the IL-7 receptor (*IL7R*) could exist in malignant T-cells. We eventually found that around 9% of T-ALL patients display somatic gain-of-function mutations in exon 6 of *IL7R*. The mutations create, in most cases, a *de novo* unpaired cysteine in the transmembrane to extracellular juxtamembrane region, resulting in disulfide bond-dependent homodimerization of two mutant receptors and consequent constitutive activation of downstream signaling with ensuing cell transformation *in vitro* and tumorigenic ability *in vivo*. Is the oncogenic potential of deregulated IL7R-mediated signaling restricted to mutated receptor? Our unpublished studies showing that conditional tetracycline-inducible IL7R transgenic mice eventually develop leukemia upon treatment with doxycline, suggest otherwise and indicate that continued expression of the wild type receptor can also display oncogenic potential. Overall, our results reveal that IL-7/IL-7R-mediated signaling is an important oncogenic axis in T-cell leukemia.

S07.2

Netherton syndrome and links to eczema

A. Hovnanian[1,2,3];
[1]INSERM U781, Paris, France, [2]Department of Genetics, Necker hospital, Paris, France, [3]University Paris Descartes - Sorbonne Cite, Imagine Institute, Paris, France.

Netherton syndrome (NS) is a rare autosomal recessive orphan disease with severe skin inflammation and scaling, a specific hair shaft abnormality and constant allergic manifestations with high serum IgE levels. NS results from loss-of-function mutations in *SPINK5* (serine protease inhibitor of Kazal type 5) encoding LEKTI-1 (lympho-epithelial Kazal type related inhibitor type 5), a 15-domain protease inhibitor expressed in stratified epithelia and in Hassall's corpuscles in the thymus. *In vitro* and *in vivo* studies in murine models and in NS patients have implicated unopposed activity of kallikrein (KLK) 5, KLK7 and elastase 2 with dual consequences on skin homeostasis. The skin barrier is severely disrupted secondary to stratum corneum detachment, increased profilaggrin processing and abnormal lipid lamellae. This leads to increased skin permeability, enhanced allergen and microbe penetration which favor skin allergy and inflammation. Danger signals are also generated, resulting in the production of IL-1 beta which contributes to skin inflammation. In parallel, KLK5 activates PAR2 which leads to the activation of the NF-kappa B pathway and the production of pro-allergic (Thymic Stromal Lymphopoietin) and pro-inflammatory (TNF-alpha) cytokines. These molecules, in concert with TARC and MDC, induce skin allergy and inflammation with severe itching and systemic involvement.
These results have identified major pathways and therapeutic targets for NS. Importantly, they have also established a link with the frequent and more complex disease atopic dermatitis, which shares several common features with NS. These include enhanced proteolytic activies, skin barrier defect through filaggrin mutations, abnormal lipid composition, PAR-2 mediated allergy and inflammation. Recent functional studies reporting defective protease inhibition caused by the frequent E420K LEKTI variant, further support the notion that *SPINK5* plays a role in eczema through a complex network involving multiple genes and/or interactions with the environment, with potential therapeutic implications.

Artificial Skin
M. del Rio[1,2,3];
[1]*Department of Bioengineering. Universidad Carlos III de Madrid, Madrid, Spain,* [2]*CIEMAT, Madrid, Spain,* [3]*Centre for Biomedical Research on Rare Diseases (CIBERER), Madrid, Spain.*

The skin is the subject of more than 400 rare inherited diseases or genodermatoses which together represent a significant part of the dermatological clinical practice. Our group is devoted to diagnostic, modeling and development of advanced therapies for some of the most relevant genodermatoses. Among that group, Epidermolysis Bullosa (EB) comprises a set of skin fragility disorders characterized by defective adherence of the epidermis to the underlying connective tissue. We have mainly focused in the recessive dystrophyc form of EB (RDEB) due to mutations in *COL7A1* coding for type VII collagen. Our studies led us to the disclosure of one of the world's most recurrent mutation, c.6257insC, affecting nearly half of the Spanish RDEB population and due to a founder effect. Recent work led us also to demonstrate revertant mosaicism within the RDEB patient population which tends to be more common than previously expected. Using optimized skin bioengineering approaches we have been able to establish skin humanized mouse models of EB suitable for cell and gene therapy testing. In addition, we have shown the feasibility of using naturally gene revertant EB cells as a source for autologous skin transplantation. My talk will also cover the use of analogous strategies, as those described for EB, to the modeling and treatment of other genodermatoses including Lamellar Ichtyosis and Xeroderma Pigmentosus as paradigmatic examples of epidermal differentiation and DNA repair defects, respectively. We hope we can contribute to the goal of having 200 new treatments for rare genetic diseases by the year 2020.

S08.1
Dissecting the effects of selection in the human genome: the case of immunity to infection
L. Quintana-Murci;
Institut Pasteur-CNRS, Paris, France.

Because infectious diseases have been paramount among the threats to health and survival throughout human history, natural selection is expected to act strongly on host defence genes, particularly on innate immunity genes. Searching for evidence of selection targeting innate immunity represents therefore an indispensable complement to clinical and epidemiological approaches for identifying functionally important genes involved in host immunity to infection and disease outcome. In the past years, we have initiated an evolutionary dissection of genes and pathways involved in innate immunity in humans. We focus on major families of innate immunity receptors, such as TLRs, RLRs and NLRs, and other molecules involved in the signalling pathways triggered by them, such as adaptors and effectors molecules, such as TIR-containing adaptors and IFNs. Although the biological role in host defence for some members of these families has been well characterised, the biological function of many others (e.g. most NALP members of the NLR family) remain poorly understood, with little knowledge about their immunological relevance. I will present different cases of how some of these genes have been targeted by strong purifying selection, attesting to their essential and nonredundant functions, while others evolve under much relaxed selective constraints, suggesting higher redundancy in host defence. I will also present some examples of molecules (e.g. TLR1, type III IFNs, etc.) that display geographically-restricted signatures of positive selection in specific human populations, indicating that genetic variation at these genes has conferred a selective advantage to the host. Finally, I will discuss our most recent findings about population variation in microRNA transcriptional responses to infection and the extent to which such variation is under genetic control (miR-eQTLs). More generally, I will discuss how adopting an evolutionary, population and cellular genomics approach can provide important insight into immunity genes playing a major role in host survival, and highlight host pathways and mechanisms playing an essential role in pathogen resistance.

Gene dosage sensitivity and copy-number evolution
A. McLysaght;
Dublin, Ireland.

A significant subset of genes in vertebrate genomes are under dosage constraint. Duplications that disturb their abundance in the cell are deleterious and are the likely cause of pathogenicity of CNVs associated with disease. What factors influence dosage sensitivity, be it haploinsufficiency or dosage-balance? What biological processes are most likely to be dosage-sensitive? How does gene dosage sensitivity influence evolutionary patterns, and how can evolutionary analyses identify these genes?

Adaptive immunodeficiency and gene therapy treatment
A. Fischer;
INSERM U768 & Unité d'Immunologie Hématologie Pédiatrique, Hôpital Necker-Enfants Malades, Université Paris Descartes ; Imagine Institute, Paris, France.

Over the last 20 years, the genetics and pathophyiology of many primary immunodeficiencies (PID) have been unraveled. This offers the opportunity to treat the most severe of these conditions by gene transfer into hematopoietic stem cells. Primary T cell immunodeficiencies appear as the best therapeutic targets because of the expected selective growth advantage conferred by gene expression into T cell precursors combined with the very long life span of T lymphocytes. Based on this rationale, ex vivo retroviral gene transfer into hematopoietic progenitors has been shown to lead to sustained (over 14 years) correction of severe combined immunodeficiency (SCID). The advent of genotoxicity events in some patients has initiated the development of modified vectors, i.e. "SIN vector" in use over the last 3 years with efficacy and safety to treat SCID as well as other PID such as the Wiskott Aldrich syndrome.

Newborn screening; what is possible, what do we want?
B. Wilcken;
The Children's Hospital at Westmead and University of Sydney, Sydney, Australia.

The first trial of Guthrie's test for phenylketonuria was completed in 1963; this year we celebrate 50 years of newborn screening. Mass screening of newborns has been found economically feasible for a wide variety of conditions where there is a marker compound detectable in blood. In most

developed and some less-developed countries all newborns are tested for congenital hypothyroidism, plus phenylketonuria and several other conditions. With the advent of tandem mass spectrometry in the mid-1990s over 50 disorders are now sought in many jurisdictions.
Problems encountered and not yet completely solved include: developing rational systems and criteria for selecting disorders for screening; adequate long-term follow-up to assess benefit, with cessation of programmes where benefit cannot be shown; development of national data-bases; the detection of mild phenotypes, and development of definitions to enable recognition of which cases need treatment. Poor availability of confirmatory tests and treatments are limiting factors in less-well-off countries.
The pressure to include new disorders is driven by new treatments for previously untreatable conditions, and advances in technology making screening feasible. Some of the disorders newly being screened for include several lysosomal storage disorders, severe combined immunodeficiencies and recently a trial of screening for X-linked adrenoleukodystrophy. In the future, perhaps quite soon, primary DNA mass testing may become affordable, which will pose many problems. Already we are poised for a second major expansion of screening due partly to advances in mutation-specific treatment of various kinds. This applies particularly to Duchenne muscular dystrophy. Disorders being actively considered include Rett Syndrome, Fragile X, long QT syndrome, and spinal muscular atrophy.
A major problem for the future will be re-defining the aims of newborn screening. There will be pressure to screen for adult-onset disorders and for prediction of risk. Development of economical systems to enable effective mass screening at later ages would be welcome.

S11.1
Mousemodels of Down syndrome

Y. Hérault[1,2,3];
[1]Institut de Génétique et de Biologie Moléculaire et Cellulaire (IGBMC), CNRS, INSERM, Université de Strasbourg, UMR7104, UMR964, Illkirch, France, [2]Transgenese et Archivage Animaux Modèles, TAAM, CNRS, UPS44, Orléans, France, [3]Institut Clinique de la Souris (ICS), GIE CERBM, Illkirch, France.

More than 50 years after the discovery of Trisomy 21, the underlying basic genetic of the Down syndrome (DS), is still not completely understood. The current working hypothesis is based on interactions between "dosage sensitive" genes located along the HSA21 that are responsible for the complex features of the pathology.In order to identify the genes involved in Down syndrome features, we created new partial trisomies in the mouse for regions homologous to HSA21 contributing to the Aneuploid zoo of DS models. Here we will report the characterization of new mouse models for various regions of interest with a specific standardized behavioral pipeline and the identification of the cystathionine beta-synthase (Cbs) in learning and memory deficits observed in Down syndrome mouse models. Using two genetic experiments we evaluated the role of Cbs in the trisomy. First we reduced the copy number of Cbs using a knock-out allele in the Abcg1-U2af1 trisomic model. We found that specific learning and memory phenotypes were rescued in compound mice showing that Cbs is required for these phenotypes. Then we generated a conditional transgenic mouse line to direct the sole overexpression of the human CBS gene in the hippocampus and the cortex. These new transgenic mice displayed similar phenotypes to the trisomic mouse lines. Thus we conclude that Cbs gain of function in the brain is sufficient to induce learning and memory phenotypes in DS. The data generated are challenging our current knowledge on the role of Cbs in the physiopathology of the disease, highlighting cross-talks in drug targets and showing the interaction of several loci in DS cognitive traits. We will discuss how this new knowledge would reinforce the development of new therapeutic approaches to facilitate the life of DS people and might help to evaluate promising strategies.

S11.2
Protein Degradation in Health and Disease

T. Hoppe;
CECAD at the Institute for Genetics, University of Cologne, Cologne, Germany.

Cellular differentiation, developmental processes, and environmental factors challenge the integrity of the proteome in every eukaryotic cell. The maintenance of protein homeostasis involves the degradation of misfolded and damaged proteins, and is essential for cellular function, organismal growth, and viability. The UPS is one major proteolytic component of the cellular proteostasis network regulating the degradation of damaged proteins that accumulate upon stress and during aging. Selective turnover of substrate proteins is initiated by covalent attachment of the conserved protein ubiquitin predominantly to internal lysine residues. This ubiquitylation step is mediated by an enzymatic cascade that involves ubiquitin-activating enzymes (E1), ubiquitin-conjugating enzymes (E2), and ubiquitin protein ligases (E3). Deubiquitylation enzymes (DUBs) modulate the size and topology of polyubiquitin chains, formed by isopeptide bonds between ubiquitin monomers. A chain of four to six ubiquitin moieties efficiently targets a substrate for degradation by the 26S proteasome. The 26S proteasome is a multi-catalytic protease complex composed of a barrel-shaped 20S proteolytic core particle (CP) and a 19S regulatory particle (RP) that translocates substrates into the 20S CP where they are degraded into short peptides.
It is commonly thought that an age-related impairment of protein degradation affects general proteostasis networks, causing enhanced accumulation of damaged proteins that can be cytotoxic and shortens lifespan (Hoppe, 2010). The activity of the 26S proteasome progressively declines during the aging process although the exact molecular aspects of this regulation have not been addressed. Beside the requirement of proteasomal integrity for normal lifespan, the identification of ubiquitin-dependent degradation pathways that specifically control the stability of lifespan regulators further reflects a key role of the UPS in the aging process. For example, different E3 ubiquitin ligases regulate the activity of the FOXO transcription factor (TF) DAF-16, which is central for insulin/insulin-like growth factor 1 (IGF-1) signaling (IIS). A novel mechanistic link between protein degradation and longevity based on deubiquitylation of polyubiquitylated substrate proteins will be discussed (Kuhlbrodt et al., 2011). Interestingly, ubiquitin-mediated degradation pathways are also involved in muscle myosin assembly and age-related muscle-degeneration (Hoppe et al., 2004; Janiesch et al., 2007; Gazda et al., 2013).

S11.3
From bedside to bench: a Fragile X patient mutation yields insights into the functional specialization of the FXR protein family.

Z. Okray, ***B. Hassan***;
VIB and University of Leuven Medical School, Leuven, Belgium.

The most prevalent basis for FMR-1 deficiency in Fragile X (FXS) patients is epigenetic silencing mediated by promoter-proximal CGG repeat expansions. Other instances of the disease phenotype have been associated with mutations in the coding regions of the FMR-1 gene, however, only one of these mutations has been experimentally characterized.
To further investigate how coding mutations in FMR-1 can contribute to FXS etiology, we screened a small group of patients who display typical FXS symptoms, yet do not harbor CGG repeat expansions in the FMR1 locus. In one patient, we recovered a mutation - a single base insertion - in exon 14 of FMR1. The mutation alters the open reading frame, creating a novel amino acid sequence in the C-terminus, followed by a premature stop codon. We find that the novel C-terminus peptide encodes a functional, bipartite nuclear localization signal (NLS), which bears a striking resemblance to the nucleolar localization signals identified in FMR1 paralogs, referred to as the FXR1 and FXR2 proteins. This signal targets the patient FMR1 protein to the nucleolus in cultured human and rat cells. Using the D.melanogaster model, we demonstrate that the presence of the patient NLS motif on FMRP can alter its function in neurons and lead to neomorphic phenotypes in vivo. Taken together, our results provide evidence for novel changes in FMRP function conferred by this clinically relevant point mutation

S12.1
The geneticist's perspective
A. Read;
Genetic Medicine, University of Manchester, Manchester, United Kingdom.

Genetics has two points of contact with the criminal justice system: DNA identification, and the possible role of genetic predisposition in antisocial behaviour. DNA profiling has brought much-needed objectivity into criminal investigation - but it is important to remember that the mere presence of a person's DNA at a crime scene tells us nothing about how or when that DNA got there or what, if anything, its owner was doing at the time. Scientific questions can arise when techniques are pushed to their limits to analyse small, mixed and degraded samples, while some feel that investigative techniques like familial searching raise specific ethical issues.
Once a case comes to trial geneticists have sometimes been asked to testify that a genetic variant possessed by the accused predisposes them to criminal behaviour. Might this make them less responsible for their actions? The popular press loves the idea of a 'criminal gene' - but how convincing is the evidence that XYY men or men with monoamine oxidase A deficiency are 'born criminals'? Are genetic predispositions any different from the innumerable other factors that can influence a person's behaviour? Might it be that the main reason genetic arguments are introduced into criminal trials is not to help the court judge criminals appropriately, but to to bamboozle juries with impressive-looking science?

A. Read: None.

S12.2
Narrowing down the free-will compass? A social and ethical perspective
M. Levitt;
Lancaster, United Kingdom.

Assumptions and outcomes of behavioural genetics have consequences for attributing responsibility and blame. These are not only central elements in the justice system but are also rooted in social and moral reasoning. In most legal cases so far genetic evidence on levels of MAOA expression has been assumed by defence lawyers to be of potential benefit to their clients, however, it could also be used against them. Notions of human agency, free-will and determinism, choice and control are discussed in relation to genetic and environmental defences for violent and antisocial behaviour. The implications of determinist accounts of violent crime for victims,offenders, the justice system and society as a whole are considered. The lecture will draw on both public and expert understandings. The public's understandings of the causes of criminal behaviour and attachment of blame, fairness and responsibility are critical to their acceptance of policy and practice in this area and to their role as lay jurors.

iPS for modelling diseases and drug screening : the example of Steinertmyotonic dystrophy
C. Martinat*, S. Nédelec, Y. Maury, J. Come, M. Peschanski;*
INSERM/UEVE UMR 861, I-STEM, AFM, Evry, France.

The lack of existing models of pathologic tissues has rendered many important questions in disease pathogenesis inaccessible. Human embryonic stem cells derived from affected embryos during a pre-implantation diagnostic (PGD), as well as the technical development to obtain human induced pluripotent stem cells generated from patients, offer the unique opportunity to have access to a large spectrum of disease-specific cell models. Disease-specific pluripotent stem cells capable of differentiation into the various tissues affected in each condition could undoubtedly provide new insights into the pathological mechanisms by permitting analysis in a human system. These new disease-specific cell models are applicable for a wide systemic mechanistic analysis ranging from functional studies at the cellular level to a large-scale functional genomics screening.
As a proof of principle, we demonstrated that PGD-derived hES cells and derivatives which, express the causal mutation implicated in the Myotonic Dystrophy type 1 (DM1), may mimic molecular defects associated to the pathology, such as the nuclear aggregation of mutant RNA.
By taking advantage of this pertinent cellular model, we identified, through a genome-wide analysis, two early developmental defects in genes involved both in myogenesis as well as in neurite formation and establishment of neuromuscular connections. These neuropathological mechanisms may bear clinical significance as related to the functional alteration of neuromuscular connections associated with DM1.
In parallel to these functional pathological studies, we developed two different approaches to identify new therapeutic strategies. The first one was based on a high content screening approach. A pilot drug screening experiment has been successfully conducted in order to identify new molecules which, due to their ability to disrupt the nuclear mutant RNA aggregation, might represent new therapeutic strategies. The second strategy used a genomics screening based on gene knockdown approach. This analysis allowed the identification of a potentially druggable target protein, inhibition of which tends to normalize molecular defects associated to DM1.
All this study demonstrated that these PGD hES–derived cell models could be relevant for wide analysis ranging from the study of the dysfunction of an inter-cellular nerve-muscle system to high-throughput functional genomics screening. Altogether, our results indicate that disease-specific hES cell lines could be used for resources driven large-scale analysis, in complement to classical approach based on the analysis of candidate gene, that could highlight the development of new therapeutic strategies.

S13.3
IPS cells to model genetic diseases and individual variability.
M. Brimpari[1], F. Rouhani[2], N. Kumasaka[2], a. Bradley[2], D. Gaffney[2], ***L. Vallier[3];***
[1]Cambridge University, Cambridge, United Kingdom, [2]Wellcome Trust Institute, Cambridge, United Kingdom, [3]Cambridge University and Wellcome Trust Institute, Cambridge, United Kingdom.

Human induced pluripotent stem cells are generated from somatic cells reprogrammed by overexressing transcription factors. Their pluripotency status confers upon them the capacity to proliferate indefinitely in vitro while maintaining their capacity to differentiate into a broad number of cell types. hIPSCs represent an unique opportunity for regenerative medicine since they could enable the production of patient specific cell types which are fully immuno-compatible with the original donor thereby avoiding the use of immune suppressive treatment during personal cell based therapy. In addition, hIPSCs can be generated from somatic cells isolated from patients suffering from diverse diseases. Then, the resulting "diseased" hIPSCs can be differentiated into the cell type targeted by the disease and thus provide in vitro models to perform large scale studies impossible with primary cell culture or with biopsy material. However, hIPSC lines appear to strongly vary in their capacity of differentiation and the origin of this variability remains unclear. Here we derived a panel of hIPSC lines from a diversity of healthy individuals and then defined their capacity to differentiate into the three germ layers endoderm, mesoderm and ectoderm from which all the adult organs are derived. This analysis revealed that most of hIPSC lines can differentiate efficiently into these primary tissues. However, a limited number of lines were resistant to specific type of differentiation. We then performed functional experiments associated with genome wide analysed to uncover the mechanisms involved. We observed that several aspect influence the capacity of individual hIPSC line to differentiate into specific tissues including the method of reprogramming, epigenetic memory but more importantly genetic variability. Therefore, these results suggest that hIPSCs could represent an unique system to model individual phenotypic variability in vitro.

S14.1
DNA repair and microcephaly

M. O'Driscoll;
Brighton, United Kingdom.

Mammalian embryonic neurogenesis is exquisitely sensitive to perturbations in cell cycle dynamics. The origins of these perturbations are multifactorial and often interconnected. Severe microcephaly can occur as a consequence of reduced cell division and/or elevated apoptosis in the developing neuroepithelium. Interestingly, defects in genes encoding centrosome, centrosomal-associated and spindle pole proteins are currently the most frequent cause of Primary Microcephaly (PM) and Microcephalic Primordial Dwarfism (MPD) syndromes in humans. The centrosome is an important microtubule-organizing centre essential for coordinating G2-M progression and normal mitotic cell division as well as the DNA damage response. Mitotic progression and segregation defects, microtubule spindle abnormalities and impaired DNA damage-induced G2-M cell cycle checkpoint proficiency have all been reported in these genetically heterogeneous patient-derived cell lines. Interestingly, congenital defects in the ATR-dependent DNA damage response (*ATR-ATRIP Seckel syndrome*) and in DNA replication licensing machinery (*Meier-Gorlin syndrome*) are also associated with centrosome abnormalities and *vice versa*, suggestive of a multifactorial but interconnected underlying pathobiology of MPD. I will present a brief overview of these defects, specifically focusing on mechanisms of genomic instability but also highlighting some unanticipated impacts of some of these defects upon signal transduction. Collectively, these findings help contribute to our evolving understanding of genotype-phenotype relationships.

S14.2
Apparently balanced chromosome rearrangements in human development

C. C. Morton[1], *J. Rosenfeld*[2], *A. M. Lindgren*[3], *S. Pereira*[3], *I. Blumenthal*[4], *C. Chiang*[4], *L. G. Shaffer*[5], *J. F. Gusella*[6], *M. E. Talkowski*[6];
[1]*Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States,* [2]*Signature Genomic Laboratories, Spokane, WA, United States,* [3]*Brigham and Women's Hospital, Boston, MA, United States,* [4]*Massachusetts General Hospital, Boston, MA, United States,* [5]*Genetic Veterinary Sciences, Spokane, WA, United States,* [6]*Massachusetts General Hospital and Harvard Medical School, Boston, MA, United States.*

Apparently balanced chromosomal rearrangements are an invaluable biological resource for annotation of the human genome and the foundation of the Developmental Genome Anatomy Project (DGAP, dgap.harvard.edu). Implementation of next-generation sequencing of rearrangements has facilitated rapid gene discovery for structural and neurodevelopmental (NDD) disorders. Structural disorders elucidated include those from subjects with various craniofacial abnormalities and brain, ocular, auditory, kidney, and bone aberrations, with validation in subjects with overlapping phenotypes or in animal models. Validation of genes in subjects with NDD has been difficult historically but is now feasible taking advantage of convergent genomic evidence. Rearrangement breakpoints were sequenced in 38 subjects with NDD and validation performed using copy number variants (CNVs) in 19,556 cases and 13,991 controls. Genes disrupted within microdeletion syndromes included *SATB2* (2q33.1), *MBD5* (2q23.1) and *EHMT1* (9q34.3), all of which are transcription and epigenetic regulators. In a follow-up study among an international network of investigators, 65 independent 2q23.1 microdeletions were ascertained, defining the role of *MBD5* as necessary and sufficient in the 2q23.1 microdeletion syndrome. Disrupted loci in some subjects associate with a spectrum of developmental and psychiatric disorders, including mental retardation, autism, language delay, schizophrenia, psychosis, cognitive impairment, and bipolar disorder, bridging phenotypes with genetic etiologies. Genes at breakpoints novel for correlation with NDD have diverse functions from methylation and transcriptional regulation to cell signaling, cell adhesion, and nonsense-mediated decay. In addition, a number of observations were made from the sequence analysis concerning genomic architecture of constitutional rearrangements including complex events akin to chromothripsis in neoplasms, nonhomologous end joining as a predominant mechanism and the presence of inversions in derivative chromosomes at sites of rearrangement. Nucleotide level resolution of apparently balanced rearrangements through next-generation sequencing can contribute to diagnostic precision in abnormal human phenotypes leading to improved genetic counseling, and can illuminate underlying genomic molecular mechanisms.

S14.3
Post-zygotic mosaicism for large scale chromosomal aberrations among elderly people; What does it mean?

J. P. Dumanski;
Dept. of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden.

Post-zygotic, acquired with age mutations in normal cells represent understudied aspect of genome biology. Human post-zygotic mosaicism has been studied in embryos, aborted fetuses, children with developmental defects and in cancer. However, little is still known about the type and frequency of acquired genetic aberrations in normal cells from subjects in the general population, especially from cohorts that are well stratified by age. Our recent analyses suggest that such mosaicism is surprisingly common, with the highest estimate of 3.5% for elderly/old subjects being affected by various large-scale aberrations. We have now extended the above analyses and studied 1153 men using blood collected at the ages of 70.7-83.6 years from the Swedish ULSAM population-based cohort that was clinically followed for more than 20 years. We applied 2.5M-Omni Illumina chip with strict selection by genotyping quality and these 1153 samples were selected out 1217 samples originally submitted as a single batch to the genotyping facility. We used the following size of cut-offs for scoring of aberrations: gains - $\geq$ 250 kb; deletions and CNNLOH - $\geq$ 10 kb. Overall, we observed a very high frequency of post-zygotic mosaicim; 42.7% of people displayed at least one aberration with gains as the most common type of aberration. Our results illustrate the high frequency and importance of post-zygotic mosaicism in normal cells, which should be studied further for associations with various diseases.

J.P. Dumanski: None.

S15.1
Drugs and genes - an overview

A. K. Daly;
Newcastle University, Newcastle upon Tyne, United Kingdom.

Individual genetic profiles affect both efficacy of prescribed drugs and susceptibility to adverse drug reactions. Serious adverse drug reactions are generally rare but occur with a range of different prescribed drugs. These reactions can affect a number of different physiological systems and tissues in the body. Progress has been made recently in understanding both their genetic basis and underlying mechanisms. During drug development, idiosyncratic adverse reactions affecting the liver are a major reason for drug attrition during the later stages of development. They are also a rare but serious complication of treatment with a number of commonly prescribed drugs, especially antimicrobial agents. Highly significant associations with particular HLA class I and class II genotypes have been reported for drug-induced liver injury with several specific drugs, for example flucloxacillin and co-amoxiclav. Examples of these associations and possible underlying mechanisms, including how this may relate to reported HLA associations for other types of adverse drug reactions, will be considered. Not all forms of idiosyncratic drug-induced liver injury reactions show HLA gene associations. Genes relevant to the innate immune system and to drug disposition appear to represent additional risk factors for drug-induced liver injury but, as with the adaptive immune system associations involving HLA, risk factors will be drug or, in some cases, drug class dependent. Overall understanding of the genetic basis of drug-induced liver injury remains limited and our ongoing studies, which are concerned with increasing case numbers and performing further genome-wide association studies combined with exome sequencing, will be discussed.

S15.2
An immunological basis for pharmacogenetic associations in the MHC

J. McCluskey*, Patricia T. Illing, Julian P. Vivian, NadineL. Dudek, Lyudmila Kostenko, Zhenjun Chen,, Mandvi Bharadwaj, John J. Miles, Lars Kjer-Nielsen, Stephanie Gras, Nicholas A. Williamson,, Scott R. Burrows, Anthony W. Purcell, Jamie Rossjohn,, Monash University and QIMR, QLD;*
The University of Melbourne, Melbourne, Australia.

Human Leukocyte Antigens (HLA) are highly polymorphic proteins that initiate immunity by presenting pathogen-derived peptides to T cells. HLA polymorphisms mostly map to the antigen (Ag)-binding cleft, thereby diversifying the repertoire of self- and pathogen-derived peptide Ags selected by different HLA allotypes. A growing number of immunologically-based drug reactions, including abacavir hypersensitivity syndrome (AHS) and carbamazepine-induced Steven-Johnson's syndrome (SJS), are associated with specific HLA alleles. However, little is known about the underlying mechanisms of these associations, including AHS, a prototypical HLA-associated drug

reaction occurring exclusively in individuals with the common histocompatibility molecule, *HLA-B*57:01,* and with a relative risk of >1000. We show that unmodified abacavir binds non-covalently to HLA-B*57:01, lying across the bottom of the Ag-binding cleft and reaching into the F-pocket where a C-terminal tryptophan typically anchors peptides bound to HLA-B*57:01. Abacavir binds with exquisite specificity to HLA-B*57:01, changing the shape and chemistry of the Ag-binding cleft, thereby altering the repertoire of endogenous peptides that can bind HLA-B*57:01. In this way, abacavir guides selection of new endogenous peptides, inducing a dramatic alteration in 'immunological self'. The resultant peptide-centric 'altered self' activates abacavir-specific T-cells, thereby driving polyclonal $CD8^+$ T cell activation and a systemic reaction manifesting as AHS. We also show that carbamazepine, a widely used anti-epileptic drug associated with hypersensitivity reactions in *HLA-B*15:02* individuals, binds to this allotype, producing alterations in the repertoire of presented self-peptides. These findings simultaneously highlight the importance of HLA polymorphism in the evolution of pharmacogenomics, perhaps providing a general mechanism for some of the growing number of HLA-linked hypersensitivities that involve small molecule drugs, but also suggesting novel pathway for induction of autoimmunity.

Moving into and inside cilia: the awesome power of diffusion

D. K. Breslow[1], F. Ye[1,2], E. F. Koslover[3], A. J. Spakowitz[3], W. Nelson[1,2], ***M. V. Nachury[1];***
[1]Department of Molecular and Cellular Physiology, Stanford University, Stanford, CA, United States, [2]Department of Biology, Stanford University, Stanford, CA, United States, [3]Department of Chemical Engineering, Stanford University, Stanford, CA, United States.

The primary cilium is a signaling organelle with a distinct complement of membrane and soluble proteins. How specific proteins are concentrated within cilia while others remain excluded is a major unanswered question. We have now established a method for selective permeabilization of the plasma membrane that leaves the ciliary membrane intact, thus enabling a quantitative and mechanistic analysis of protein entry into primary cilia. Using a diffusion-to-capture assay, we find that soluble proteins larger than 75 kDa fail to enter cilia and that the ciliary permeability barrier is mechanistically distinct from the nuclear pore complex. Applying a mass transport model to this system reveals diffusion coefficients for soluble proteins that are compatible with a rapid exploration of the ciliary space in the absence of active transport.
We extend our conclusions to membrane protein by conducting single molecule imaging of signaling receptors inside cilia. Here, we find that membrane proteins move along primary cilia by a combination of diffusion and motor-driven transport. Perturbation of either diffusion or active transport shows that cargo movements can be uncoupled from movements of the intraflagellar transport (IFT) machinery, and that diffusion is sufficient for membrane proteins to explore the ciliary surface. Taken together, our results indicate that signaling within cilia need not be entirely reliant on active transport and poses the question of the true function of IFT.

Educational Sessions

ES1.1
Sequencing at The Wellcome Trust Sanger Institute in the year 2013

M. Quail;
Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The Wellcome Trust Sanger Institute is powered by sequencing. What are we using all this sequencing for? How is sequencing changing? How do we manage and process the many thousands of samples that we sequence? What technologies are we employing for different applications? What are we developing in our R&D group? In my talk I will describe our sequencing pipelines, optimisations and new protocols for Illumina library preparation and describe our progress, experiences and optimisation of semiconductor and third generation sequencing platforms.

M. Quail: None.

ES1.2
Performance and Improvements in Analyzing Next Generation Sequencing Technologies

H. Tilgner[1], D. Sharon[1], D. Xie[1], V. Kuleshov[2,3], R. Chen[1], D. Pushkarev[3], K. Karczewski[1], A. P. Boyle[1], T. Blauwkamp[3], M. Kertesz[3], R. Chen[4], H. Lam[4], M. Pratt[4], G. Bartha[4], J. Harris[4], J. West[4], ***M. Snyder[1];***
[1]Department of Genetics, Stanford University School of Medicine, Stanford, CA, United States, [2]Department of Computer Science, Stanford University, Stanford, CA, United States, [3]Illumina, Inc., 5200 Illumina Way, San Diego, CA, United States, [4]Personalis Inc., Menlo Park, CA, United States.

We have explored different high throughput sequencing technologies for analyzing human genomes, exomes and transcriptomes. For genomes and exomes we have compared different sequencing technologies and capture methods respectively and evaluated their performance. Limitations of the different platforms were discovered and managed to improve sequence accuracy and coverage, particularly in regions of high clinical relevance. We have also utilized and evaluated new long sequence technologies (e.g. Moleculo/Illumina) for accurate phasing of genome variants and calling of structural variants.
In addition to genome and exome analyses, we have explored different long reads technologies (PacBio, 454) for accurate mapping of transcriptomes. These studies have revealed that many full length transcripts can be revealed using long read sequencing and resulting in accurate and novel transcript definition.
Together the different technologies produce more accurate and comprehensive genomes, exome and transcriptome sequences. An example of using an accurate phased genome for analyzing methylomes will be presented.

ES2.1
Integration of Microarray Technology into Prenatal Diagnosis

R. Wapner;
Columbia University, New York, NY, United States.

New genetic technologies have quickly entered obstetrical care providing an ever-increasing amount of information about the fetus. Less than 5 years ago, karyotyping was the predominant tool for genetic evaluation of the fetus and was used predominately for aneuploidy detection and the identification of relatively large genomic changes of 7-10 million base pairs or larger. More recently, microarray technology has been introduced into prenatal evaluation and has the ability to identify much smaller genomic changes (microdeletions and duplications). With this increased resolution has come the knowledge that smaller findings also have significant clinical implications and are not infrequent in routine prenatal testing.
This genetic knowledge has allowed improved counseling for pregnancies identified with fetal structural anomalies, in which approximately 6% of such cases with a normal karyotype will have a genomic cause identified by microarray testing. Approximately 1% or more of structurally normal pregnancies also have clinically relevant genomic findings, suggesting that all pregnant couples should consider invasive testing with microarray analysis.
This increasing ability to evaluate the fetal genome comes with significant responsibility for clinicians. These technologic advances have rapidly out-

paced our ability to thoughtfully and appropriately use the information. Pretest and post-test counseling must be adapted so they are informative, prepare patients for the reproductive decisions they must make, and still be able to be accomplished within a feasible and timely period.

R. Wapner: None.

ES2.2
New approaches in preimplantation screening

S. Munné;
Livingston, NJ, United States.

ES3.1
Understanding Genomics. Trends in Science Communication

A. M. Dijkstra;
University of Twente, Science Communication, Enschede, Netherlands.

Nowadays, publics are becoming more critical towards new technologies, as has been shown with biotechnology and genomics. The relationship between science, technology and society is changing. Society changes and publics are articulating their opinions more often and are expressing more critical thoughts about new developments. At the same time, science and technology are changing as well. As a result, due to related uncertainties and unknown risks, not all of these new developments are welcomed anymore. In this changing society, both politicians and researchers agree that for developing (new) technologies public acceptance and trust is vital. Current insights in literature, therefore, emphasize public engagement processes, involving publics in two-way communication and dialogue instead of educating and persuading publics. However, is more engagement really the key? How should publics understand, for example, genomics? And, what role is there for social media? Based on insights from research, trends in science communication are discussed.

A.M. Dijkstra: None.

ES3.2
Science in the media. Lost in translation

D. M. Secko;
Department of Journalism, Concordia University, Montréal, Québec, QC, Canada.

A recurring and recalcitrant theme in the discussion of science in the media concerns what is "lost" when a scientific paper becomes a news article. While some critics acknowledge the existence of great science communication, they also fiercely point to a number of broader issues, including: uncritical and over-simplistic science reporting, narrow frames of scientific progress and economic prospect, a limited range of expert opinion, preferences toward positive messages, unrealistic time lines, and media professionals engaging in cycles of hype. Some media professionals acknowledge various critiques as well, but also question whether the goals and norms of their profession in choosing what to include and what to exclude is sufficiently understood. In the communication of a complex and rapidly evolving target such as genomics, some things will inevitably be lost. This presentation will explore these inclusions and exclusions, attempting to highlight what remains in examples of inspiring science communication.

D.M. Secko: None.

ES4.1
Cancer risk in overgrowth syndromes

A. Riccio[1,2];
[1]DiSTABiF, University of Naples 2, Naples, Italy, [2]IGB-CNR, Naples, Italy.

Overgrowth syndromes (OGS) are a heterogenous group of disorders characterized by global or regional excess of growth. Many of them show increased risk of tumors requiring specific protocols for tumor surveillance. This lecture will focus on recent advances in disease gene identification which resulted in improvement of our understanding in the molecular mechanisms of childhood overgrowth. Molecular defects include both constitutional and somatic single gene defects as well as genomic imprinting abnormalities. These in turn may result from either mutations of imprinting control regions (ICR) acting in cis or arise de novo as epigenetic mutations possibly caused by stochastic events, environmental factors or mutations of regulatory factors acting in trans. Recurrence risks, clinical phenotype and tumor location and frequencies associated with different type of molecular defect will be described. New advances are expected soon from the wide application of next generation sequencing technologies to the analysis of the genome and epigenome of OGS patients. Likely, these will turn out in even larger impact in clinical medicine through the development of gene-specific follow-up protocols and therapies.

A. Riccio: None.

ES4.2
Cancer risk in RASopathies

K. Gripp;
Wilmington, DE, United States.

Rasopathies are syndromic conditions resulting from germline mutations affecting the RAS/MAPK signaling pathway. Dysregulation of this pathway's key role in cell growth and differentiation during embryogenesis gives rise to a recognizable phenotype affecting multiple organ systems, also referred to as "neuro-cardio-facio-cutaneous syndromes". Postnatal pathway dysregulation through somatic mutations similarly affects cell growth and differentiation and occurs during carcinogenesis. Given this transforming activity of RAS/MAPK pathway mutations, it is not surprising that syndromes resulting from germline mutations entail an increased malignancy risk. The relative risk, cancer type and age are syndrome specific. Neurofibromatosis type 1 is a common rasopathy, and its increased risk for optic gliomata and malignant peripheral nerve sheath tumors is addressed in surveillance recommendations. The heterogeneous Noonan syndrome is also common, and its associated increased risk for juvenile myelomonocytic leukemia (JMML) varies by specific *PTPN11* or other gene mutation. A JMML-like myelodysplastic syndrome in early childhood can have a benign course. Cardio-facio-cutaneous (CFC) syndrome may be associated with an increase in acute lymphoblastic leukemia. For Noonan and CFC syndrome, with a low absolute cancer risk, and malignancies which are not likely to show improved outcome after early detection, few screening recommendations exist. In contrast, Costello syndrome, caused by *HRAS* missense mutations, is associated with a higher tumor risk, approaching 15%. Embryonal rhabdomyosarcoma accounts for about 60% of these malignancies, followed by neuroblastoma and transitional cell carcinoma of the bladder. While screening suggestions for Costello syndrome were published, their benefit remains unknown. In conclusion, while the cancer risk is increased overall in rasopathies, the specific risk varies greatly by syndrome, and often by specific causal mutation. Awareness for the risk increase, education of patients and families, prompt evaluation and standard treatment for malignancies constitute best medical practice.

ES5.1
Spectrum of monogenic forms and clinical importance of de novo mutations

S. Baulac;
ICM, Hôpital Pitié-Salpetrière, Paris, France.

Epilepsy is one of the most common neurological disorder. It encompasses a large group of syndromes, diverse in terms of age, etiology, clinical types of seizures, disabilities and prognosis. Genetic factors play a predominant role in about 40% of all epilepsies. Rare Mendelian forms of epilepsy are now well recognized. Since 1995, family-based linkage studies have revealed numerous causative epilepsy genes (*CHRNA4*, *CHRNA2*, *CHRNB2*, *KCNQ2*, *KCNQ3*, *KCNT1*, *SCN1A*, *SCN2A*, *SCN1B*, *GABRG2*, *GABRA1*, *PRRT2*, *PCDH19*, *LGI1*, *DEPDC5*···). To date, the majority of known epilepsy genes encode neuronal ion channel subunits or neurotransmitter receptor subunits leading many of the genetic epilepsies to be considered as channelopathies. Molecular approaches have revealed great genetic heterogeneity, with the vast majority of genes remaining to be identified. This presentation will review recent findings on the progress in gene discovery in monogenic epilepsies, with particular focus on genes harboring inherited variants involved in large multiplex families and *de novo* mutations responsible for sporadic cases. The gene encoding the α1 subunit of neuronal voltage-gated sodium channels (*SCN1A*) is the most frequently mutated gene in epilepsy so far. Inherited *SCN1A* mutations are found in autosomal dominant families with Genetic Epilepsy with Febrile Seizures Plus (GEFS+), while *de novo* mutations cause a severe epileptic encephalopathy named the Dravet syndrome. Genetic testing of *SCN1A* may prevent the need for unnecessary clinical investigations and provide genetic counseling for families. Mutations in the sodium-gated potassium channel gene *KCNT1* were found in two epileptic disorders: inherited mutations are responsible for severe autosomal dominant nocturnal frontal lobe epilepsy and *de novo* mutations for malignant migrating partial

seizures of infancy, an early infantile epileptic encephalopathy. One of the most recent advances in the field of epilepsy genetics is the discovery that loss-of-function mutations of *DEPDC5* (DEP domain containing protein 5) are a frequent cause for a broad spectrum of familial focal epilepsies. The implication of a DEP domain (Dishevelled, Egl-10 and Pleckstrin domain)-containing protein that may be involved in membrane trafficking and/or G-protein signaling, opens new avenues for research.

S. Baulac: None.

ES5.2
The role of genetic susceptibility factors in epilepsy and their clinical relevance

I. Helbig;
Kiel, Germany.

While there has been exceptional progress in the identification of monogenic forms of epilepsy, the discovery of genetic susceptibility factors for seizure disorders has lagged behind, even in comparison to other neurodevelopmental disorders. Genes identified in familial epilepsies only play a minor role in common, non-familial epilepsies, a finding that has long puzzled scientists and has held back progress in understanding the genetic basis of common epilepsies. Further burdened with the phenotypic heterogeneity of the epilepsies, the field was reluctant to adapt to large-scale association studies. Epilepsy genetics is currently emerging from the "dark ages" of small and underpowered association studies with few sufficiently powered association studies published. Finally, in 2012, a large-scale genome-wide association study identified the first common risk factors for epilepsies including variants at the VRK, PNPO and SCN1A loci. In addition, the unexpected discovery of copy number variants including microdeletions at 15q13.3, 16p13.11 and 15q11.2 has pioneered the research into the role of rare genetic variants. Investigations of these risk factors both in case-control studies and family studies have emphasized relevant issues including incomplete penetrance, phenotypic heterogeneity and incomplete segregration in families. Equipped with the early experiences relating to the role of common and rare susceptibility factors, the field of epilepsy genetics is currently embarking on a journey to discover risk factors with massive parallel sequencing technologies. While there is some emerging evidence for de novo mutations particularly in epileptic encephalopathies, the full impact of de novo versus inherited risk factors remains to be determined. In parallel, the field of epilepsy pharmacogenomics is evolving rapidly and variants such as HLA B*1502 are established risk factors for adverse reactions to certain antiepileptic drugs that may already have clinical consequences.
In this presentation, we will discuss the emerging role of common and rare genetic susceptibility factors in the epilepsies, highlight current controversies and discuss the clinical implications of these findings.

ES6.1
Inherited retinal dystrophies: insights & challenges behind the rainbow

F. P. M. Cremers;
Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

In the last 25 years ~100 genes have been implicated in inherited retinal dystrophies (IRDs). X-linked RD genes were identified using linkage and deletion mapping. Linkage and homozygosity mapping facilitated IRD gene identification on autosomes. Many IRD genes encode proteins of the visual cycle and phototransduction cascade, or are orthologs of genes mutated in animal models. One-third of the IRD-associated genes encode ciliary proteins. Several IRD genes are ubiquitously expressed (e.g. *CHM*, *SNRNP200*). Many genes mutated in syndromes, are also involved in non-syndromic IRDs. Using IRDs associated with mutations in *BBS1*, *CEP290*, or *MVK* (encoding mevalonate kinase), I will illustrate our (lack of) understanding regarding genotype-phenotype correlations. To shed further light on this matter, we need additional insights in the transcriptional variation of IRD-associated genes due to *cis*- and *trans*-acting factors, but also must further explore the interplay between retinal proteins.
Based on genetic analyses of consanguineous Pakistani IRD families, >80% of the underlying genes are known. Massive parallel sequencing in recent years identified rarely mutated IRD genes such as *C8orf37* and *RAB28*, and enabled comprehensive diagnostics. Surprisingly, we identified *de novo* variants in 14% of isolated cases with retinitis pigmentosa. A shortcoming in current diagnostics is the absence of a cheap sequencing method to analyse individual patients suffering from genetically heterogeneous diseases. Challenges for the future will also be to explore non-coding regions through transcriptome and whole genome sequencing, to make sense of rare missense and synonymous variants, and to register all IRD variants in well-curated databases, such as the Leiden Open Variation Databases. As the most frequently mutated IRD genes have already been identified, there is an increasing need for large cohorts of patients. To this end, the European Retinal Disease Consortium was established, which encompasses 12 research groups in 11 countries, and has ascertained >8.000 IRD families.

F.P.M. Cremers: None.

ES6.2
Inherited retinal disease - management and therapies

A. R. Webster[1,2];
[1]Moorfields Eye Hospital, London, United Kingdom, [2]UCL Institute of Ophthalmology, London, United Kingdom.

Inherited retinal diseases comprise a large and varied group of disorders that adversely affect vision due to the perturbation of genes expressed in the specialised cells of the retina. Vast genetic and allelic heterogeneity confound accurate molecular diagnosis, a challenge now, to a degree, surmountable using high-throughput nucleotide sequencing technology. The identification of causative genes, and the molecular diagnosis in patients and families has an impact on clinical management in a number of ways. Some disorders are phenotypically distinct and immediately suggest a causative gene, and genetic segregation. However, others, such as retinitis pigmentosa, are heterogeneous, and require a molecular diagnosis before segregation and accurate counselling can be offered to patients and relatives. Once a group of patients with retinal degeneration has been molecularly defined, then this allows the acquisition of data delineating the age-related changes in retinal function and structure, important to determine effective treatment strategies, and for chosing metrics to measure the efficacy of treatment in a short a time as possible. Preliminary data on gene-replacement for disease due to mutation of REP1, causative of choroideraemia, will be presented, this being a paradigm for treatments aimed at preserving function of the fovea. This retinal region, 400-500µm in diameter, is packed exclusively with cone photoreceptors, designed specifically to allow fine visual discrimination. Data from our group on the effect on this structure, in vivo, of mutations in the ABCA4 gene, shows significant differences in degeneration, which are important in the consideration of therapies. Examples of diseases in which simple modifications might help sustain vision, based on knowledge of molecular pathology, include disorders due to mutation in ABCA4, GUCA1A and EFEMP1. Finally, the accessibility of the retina makes it tractable to approaches that attempt to restore vision. Data from our group and others show that retinal prostheses can deliver useful visual percepts in those with disease causing none, or vague, light perception. Furthermore, strategies involving cell transplantation and optogenetics show promise in the future.

A.R. Webster: None.

ES7.1
Introducing next generation technology to clinical scientists

C. Wright;
Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

High resolution genomic technologies are increasingly being used in clinical research to identify the genetic causes of a variety of human diseases. The UK-wide Deciphering Developmental Disorders (DDD) project uses exon-enriched aCGH coupled with trio exome sequencing to identify the underlying genetic aetiology in children with severe undiagnosed developmental disorders. Where likely causal variants are identified, they are fed-back to Regional Genetics Services for validation and discussion with the family. At the half-way point of this 5-year project, we have recruited over 5000 families to the study, processed over 1000 trio exomes, and fed-back ~200 potential diagnoses.
In this talk I will outline the interaction with clinical teams in DDD through DECIPHER, creation of a scalable automated analysis and variant filtering pipeline for prioritising likely causal variants, and the use of multidisciplinary clinical reporting meetings for final sign-off. I will also discuss the potential for DDD to act as a prototype for clinical translation of whole genome technology in rare diseases in the NHS, and some of the issues around incidental findings and opportunistic genome screening.

C. Wright: None.

ES7.2
Bioinformatic challenges of applying NGS in the clinic

C. Gilissen;
UMC St Radboud, Nijmegen, Netherlands.

The advent of massive parallel sequencing is rapidly changing the strategies employed for the genetic diagnosis and research of diseases that involve a large number of genes. The implementation of NGS in routine diagnostics is a challenging process in which bioinformatics plays an increasingly important role. These challenges vary from data management issues, and automation to the choice and implementation of basic analysis steps such as alignment of reads and variant calling. Specifically important considering diagnostic guidelines are bioinformatic methods for quality control, interpretation of variants and the prevention of incidental findings.
We implemented exome sequencing as a diagnostic test for five genetically heterogeneous diseases and have tried to resolve these specific challenges: we are able to automatically detect sample mix-up, poor sample quality, and limit the number of variants that require manual follow-up. Thorough comparison of the performance of our traditional Sanger based sequencing approach to our exome sequencing approach for these 5 different conditions showed that exome sequencing has a higher diagnostic yield than Sanger sequencing. Even if all genes that could have been ordered by physicians had been tested, the larger number of genes captured by the exome would still have led to an improved diagnostic yield.

C. Gilissen: None.

ES8.1
How to get published in the European Journal of Human Genetics

G. van Ommen;
Leiden, Netherlands.

The practice of publishing research in peer-reviewed journals is crucial to the advance of science and medicine. Often researchers receive no direct instruction on how to go about this, but instead are expected to pick up the correct procedures from supervisors and colleagues. We propose bringing together a panel of experts made up of *GertJan B. van Ommen*, the long term Editor of*European Journal of Human Genetics* , Joerg Schmidtke, Director of the Institute of Human Genetics at Hannover Medical School, past president of ESHG and member of the **„Genetic testing as part of health care**" unit of EuroGentest and Magdalena Skipper, Senior Editor from *Nature*. This panel will describe the whole process of publishing, from drafting a manuscript to the peer review process through to publication. As such, it will be of interest to the range of participants in the publishing process: from less experienced authors to those undertaking peer review.

ES9.1
A genetics history of our species

E. Heyer;
National Museum of Natural History, Paris, France.

I will start by presenting recent works on the history of our species based on genetic data. I will present our recent origin out of Africa, the admixture with Neandertal and Denisova. Then I will focus my talk on different evolutionary forces that have shaped our genetic diversity: natural selection, population expansions, migration. In particular, I will present some examples on the impact of cultural behaviors and their transmission on genetic diversity. This second part includes ecological inheritance through Niche construction: there are now several documented cases where, by changing our environment, we create new selective pressure. Transmission of cultural traits can also impact our genetic diversity by limiting gene flow among populations, or shaping intra-population genetic diversity. In conclusion, cultural transmission interacts with biological evolution in shaping our genetic diversity.

E. Heyer: None.

ES9.2
Tracing back geographic origine and phenotypes using genetic data

M. Kayser;
Erasmus University Medical Center Rotterdam, Rotterdam, Netherlands.

Human migration history out of Africa into (almost) all worldwide regions left various genetic footprints that can be detected in modern populations and individuals around the world. For instance, genomic signatures allow tracing back the bio-geographic origin of a population and a person either via large number of genetic markers or via specifically ascertained ancestry-informative DNA markers, which can be relevant in medical, anthropological and forensic studies and is important for mapping disease and other genes. The geographic resolution available with DNA ancestry testing varies between worldwide regions but in general larger geographic regions such as continents can be inferred from genetic data more reliably than subregions within continents. For some geographic regions the use of Y-chromosomal or mitochondrial DNA markers allows subregional paternal or maternal ancestry inference not easily provided with autosomal DNA markers. Moreover, genomic signatures shaped by evolutionary forces in combination with migration history allow a better understanding how phenotypic diversity such as appearance observed in humans around the world arose. Recent progress in the genetics of human appearance phenotypes not only delivered numerous genes, some of which show clear signatures of positive selection, but also allows to predict certain appearance traits solely from genetic data, which can be relevant in anthropological, historical and forensic studies. This talk will provide an overview on genetic population substructure around the world and how this knowledge can be used to infer the bio-geographic ancestry from a person's DNA. Furthermore, this talk will highlight the genetic basis of human appearance traits, their evolutionary history and how this knowledge can be used to predict appearance from a person's DNA.

De novo mutations in the Genome of the Netherlands

L. C. Francioli[1], *P. Polak*[2,3], *W. Kloosterman*[1], *S. Sunyaev*[2,3], *P. I. W. de Bakker*[1,2,3];
[1]*Departments of Medical Genetics and Epidemiology, University Medical Center Utrecht, Utrecht, Netherlands,* [2]*Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States,* [3]*Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, United States.*

Genome of the Netherlands Consortium

Background: The Genome of the Netherlands (GoNL) is a national effort to characterize genomic variation in the Dutch population through whole-genome sequencing of 250 families (231 trios, 19 twin quartets) at 12x using Illumina HiSeq. Sequencing was performed by BGI (China). The design of our study allowed us to investigate the role of *de novo* mutations in random individuals at an unprecedented scale.

Method: We developed a Bayesian algorithm to detect *de novo* mutations from pedigree data and implemented it as the PhaseByTransmission module in the Genome Analysis Toolkit (GATK). We validated >550 *de novo* mutation calls (Sanger, MiSeq) to estimate the false positive rate. We simulated *de novo* mutations by random injection in our sequence data to assess our false negative rate while preserving the characteristics and intrinsic biases of our data. We used machine-learning techniques to correct for these effects.

Results: We called more than 19,600 *de novo* mutations, of which 44% were called with high confidence. Validation results showed that >60% of all calls and >92% of high-confidence calls were true positives. Through simulations, we estimated that we were able to call 70% of all *de novo* mutations. We observed a strong correlation between the father's age at conception and the *de novo* mutation load in the offspring (r > 0.4). We report that *de novo* mutation properties vary throughout the genome. These results illustrate that *de novo* mutation detection and analysis of their functional relevance can be performed on medium-coverage sequencing.

C01.2

Type 2 Diabetes strongly increases risk for the pre-cancerous state of clonal mosaicism

A. Bonnefond[1], *B. Skrobek*[1], *S. Lobbens*[1], *E. Eury*[1], *S. Cauchi*[1], *O. Lantieri*[2], *B. Balkau*[3], *E. Riboli*[4], *M. Marre*[5], *G. Charpentier*[6], *L. Yengo*[1], *P. Froguel*[1];
[1]*CNRS, Lille, France,* [2]*IRSA, La Riche, France,* [3]*Inserm, Villejuif, France,* [4]*Imperial College London, London, United Kingdom,* [5]*Inserm, Paris, France,* [6]*Corbeil-Essonnes Hospital, Corbeil-Essonnes, France.*

Large chromosomal clonal mosaic events (CMEs), i.e. the co-existence of cells with two or more distinct karyotypes within an individual, have recently been suggested to be linked with aging and to predict the subsequent development of cancer. Type 2 diabetes (T2D) has been conceptualized as an accelerated ageing disease, and is associated with a higher prevalence (and mortality) of cancers. Here, we aimed to assess the impact of T2D on CME occurrence in blood.

We assessed the presence of large CME (≥5Mb) in 7,437 individuals (2,208 T2D patients; 5,229 controls) using Metabochip DNA arrays (Illumina). The effect of T2D on the occurrence of detectable CME was assessed using logistic regression adjusted for age, gender, body mass index and population stratification.

We found a strong effect of T2D on the risk of detectable CMEs (OR=5.4; P<5×10-5). The association was even stronger when we analysed non-obese T2D patients (OR=5.9; P<5×10-5). Importantly, T2D patients carrying CME had a higher prevalence of vascular complications than T2D non-carriers (71.4% versus 37.1%; P=5.0×10-4). The size of CMEs in blood and the percentage of abnormal cells were stable over a 6-year follow-up period.

We propose that the most severe forms of T2D can favor the development of CMEs which may contribute to the higher risk for cancer in the T2D population. The present study may have profound clinical implications: given the modest cost of Metabochip and the medical interest of detecting pre-cancerous states, a CME genetic testing may be proposed in diabetic patients with early-onset complications.

Static encephalopathy of childhood with neurodegeneration in adulthood (SENDA) is a recently established subtype of neurodegeneration with brain iron accumulation (NBIA)1-3. By exome sequencing, we found de novo heterozygous mutations in WDR45 at Xp11.23 in two individuals with SENDA, and three additional WDR45 mutations in three other subjects by Sanger sequencing. Using lymphoblastoid cell lines (LCLs) derived from the subjects, aberrant splicing was confirmed in two subjects, and protein expression was observed to be severely impaired in all five subjects. WDR45 encodes WD repeat protein interacting with phosphoinoside 4 (WIPI4), one of the four mammalian homologs of yeast Atg18, which plays an important role in autophagy4,5. Decreased autophagic activity and accumulation of aberrant early autophagic structures were demonstrated in the LCLs of the subjects. These findings provide the direct evidence that an autophagy defect is indeed associated with a neurodegenerative disorder in humans.

Despite recent advances in base-calling accuracy and read length, de novo genome assembly and structural variant analysis using 'short read' shotgun sequencing remain challenging. We have developed a new approach that utilizes highly parallel nanochannel arrays in which many thousands of very long single DNA molecules are linearized and imaged. This novel approach is automated on the Irys System and can scan the entire genome rapidly to generate physical maps that provide a more comprehensive view of the genome. Here we describe the genome maps of the first two diploid human genomes constructed using this approach. Two members of a CEPH-CEU trio (father and daughter, NA12891 and NA12878, respectively) genotyped and sequenced extensively as part of the International HapMap and 1000 Genomes Projects were mapped to 50X coverage with long (150 kb to >500 kb) DNA fragments fluorescently labeled at Nt.BspQI (GCTCTTCN/) sites. The resultant sequence motif maps are used to resolve haplotypes, identify structural variations, and assist in de novo sequence assembly of these two individuals. Particularly complex genomic loci, such as the major histocompatibility (MHC) region are well characterized with these maps. Our results show that the DNA sequence of these two individuals differ significantly from the reference human genome sequence and confirm the majority of the structural variants identified previously. In addition, new structural variants not detected by next-generation sequencing are easily identified. The genome mapping approach is simple and can be performed in any modern molecular genetic laboratory.

Schizophrenia has a strong genetic component, yet in most cases the underlying causes are unknown. To identify additional genetic risk factors, we have assessed the contribution of de novo mutations by sequencing the exomes of sporadic cases of schizophrenia and their healthy parents (n=54 trios). Whole exomes were captured and sequenced using the Agilent and Illumina technologies, respectively and genetic variants were called using our analytical pipeline. We identified 51 validated de novo mutations, 36 of which were predicted to alter protein structure/function including 31 missense, 2 conserved splice site, 2 nonsense mutations and 1 frameshift deletion. The observed point mutation rate of 0.94 events per trio or 1.8 x 10-8 per base per generation and the nonsynonymous to synonymous ratio of 2.19 did not differ significantly from neutral expectations. A gene ontology analysis on the genes with protein-altering de novo mutations revealed an enrichment for biological processes involved in chromatin regulation and organization, although not statistically significant probably owing to the limited number of genes analyzed. Remarkably, we found a damaging de novo mutation in RGS12 (R54L), a gene already reported as severely mutated in a similar study (Xu et al. 2012) suggesting strong candidacy as a risk factor. We currently investigate the burden and disequilibrium transmission test of damaging mutations in the candidate genes for schizophrenia, defined here. Our and other studies indicate extensive genetic heterogeneity in schizophrenia and provide a list of genes potentially involved in disease susceptibility.

On behalf of GONL consortium

The Genome of the Netherlands project (GoNL, http://nlgenome.nl) aims to create a map of genetic variants through whole genome-sequencing of 250 families representing 11 Dutch provinces. Here we report results from the analysis of structural variation employing several complementary approaches. We detected a wide spectrum of genetic variants including short indels, deletions, insertions, tandem duplications, inversions, mobile element insertions and translocations.

Short indels and structural variants (SVs). Using the consensus of 4 callers (GATK_UG, PINDEL, CLEVER and SOAPdenovo assembly) we predicted 1,196,767 small indels of which 1,413 are causing premature stop codons and frameshifts in 1,285 genes. On average, we observed 134 frameshift and 19 splice site mutations per individual genome. By combining different strategies: read depth (CNVnator, DWAC-Seq, Facade), read pair (123SV, BreakDancer), combined approaches (PINDEL, GenomeSTRiP, CLEVER), de novo assembly (SOAPdenovo) we predicted over 10 thousand variants representing different SV types and size ranges.

Validation of structural variant sets. We performed targeted resequencing to: i) determine the false-positive rate for different approaches/tools; ii) validate loss-of-function variants; iii) confirm novel genomic segments, absent in the current genome reference; iv) verify de novo structural events

Significance. In combination with GoNL SNP set (reported separately) these results comprehensively describe common genetic variants in individuals of Dutch origin. This variation catalogue is essential for understanding mechanisms of SV formation, their population dynamics and history. It provides an essential resource for the interpretation of GWAS results and the genomes of other West-European individuals with constitutional or acquired disorders.

Acrodysostosis (MIM101800) is a dominantly inherited condition associating 1) a skeletal dysplasia characterized by short stature, facial dysostosis and severe brachydactyly with cone-shaped epiphyses 2) resistance to mutiple hormones 3) moderate to mild intellectual disability. Acroscyphodysplasia (MIM250215) is rare and characterized by lower femoral and upper tibial epiphyses embedded in cup-shaped, large metaphyses, associated to severe growth retardation and brachydactyly.

Studying 22 unrelated acrodysostosis cases, we identified heterozygous de novo PRKAR1A mutations in 8 cases and heterozygous de novo PDE4D mutations in 6. Neither PDE4D nor PRKAR1A mutations were found in four patients with characteristic clinical features. The molecular screening is in progress for the four remaining cases. In 4 cases of acroscyphodysplasia, we identified PDE4D mutations.

Splitting our series based on the disease causing gene confirmed genotype-phenotype correlations. Hormone resistance was consistently observed in the patients carrying PRKAR1A mutations while no hormone resistance was observed in 5/6 patients with PDE4D mutations. Moreover, all patients with PDE4D mutations shared characteristic facial features (midface hypoplasia with the canonical nasal hypoplasia) and some degree of intellectual disability. Finally, our findings of PDE4D mutations in 4 cases of acroscyphodysplasia support also that PDE4D is responsible for a severe skeletal dysplasia, with major epiphyseo-metaphyseal changes.

Mandibulofacial dysostosis (MFD) is the consequence of an abnormal development of the first and second branchial arches. The core phenotype is represented by malar and mandibular hypoplasia and dysplastic ears. Conductive hearing loss, lower lid anomalies and/or cleft palate are frequent associated features. Recently, EFTUD2 heterozygous loss-of-function mutations have been identified in patients with MFD and microcephaly (MFDM, Guion-Almeida type, MIM610536), EFTUD2 being a protein of the spliceosome complex.
Here we report 27 patients harbouring a deletion encompassing EFTUD2 or a heterozygous mutation. This series allows us to broaden the spectrum of features ascribed to EFTUD2 loss of function and includes esophageal atresia, semi circular canal anomalies, olfactory bulb agenesis, toe syndactyly and vertebral anomalies. Until now, no syndrome featuring both MFD and EA has been clearly delineated although EA is reported in about 5% of patients diagnosed with oculoauriculovertebral spectrum (OAVS, MIM 164210). Thus, we define a novel syndromic EA entity, for which a locus at 17q had previously been suggested, and emphasize that MFDM syndrome should be considered as a differential diagnosis for phenotypic variants of CHARGE, Feingold, VACTERL syndromes, and Oculo-Auriculo-Vertebral spectrum.
Nager (MIM154400), Taybi-Linder (MIM210710) and MFDM syndromes emphasize the necessity of mRNA maturation through the spliceosome complex not only for global growth but also within specific developmental fields.

Microcephalic osteodysplastic primordial dwarfism type I (MOPD I, OMIM 210710) was initially described in 1967 by Taybi and Linder in two siblings with intrauterine and postnatal growth retardation, dwarfism, a skeletal dysplasia, severe microcephaly with developmental brain malformations and early death. Our team and others have identified mutations in a small nuclear non-coding RNA, named U4atac snRNA, a critical component of the minor spliceosome (Edery P et al, Science 2011 and He H et al, Science 2011). We have also provided evidences that MOPD I syndrome is associated with abnormal splicing of a restricted subgroup of introns of the genome, named U12 introns, which are recognized by the minor spliceosomal machinery through non-consensus U12-intron recognition sites. We are currently perfoming whole transcriptome analysis in fibroblasts derived from MOPD I patients to identify deregulated genes/signalling pathways responsible for the phenotype. Here, we provide further delineation of the clinical spectrum of MOPD I syndrome and *RNU4ATAC* molecular data in 14 patients from our series (article in preparation) and we review data on 10 other patients and a large Amish family reported since the discovery of the causative gene. To our knowledge, this is the largest and most comprehensive clinical and molecular study available in MOPD I syndrome.

Baraitser-Winter (BRWS), a dominant MCA disorder, was shown to result from heterozygous gain of function mutations in one of the two ubiquitous cytoplasmic actin-encoding genes ACTB and ACTG1 (Rivière, Nat Genet 2012, 44: 440) which are the structural components of filamentous actin (F-actin), which, together with myosin motors and actin-binding proteins, forms a thin, cross-linked network lying immediately beneath the plasma membrane. ACTB and ACTG1 are important for basic cellular processes such as cytokinesis, cell migration, and embryogenesis.. We present detailed phenotypic description and neuroimaging of 34 patients with molecularly proven BRWS, emphasizing the clinical variability of the syndrome, which also encompass Fryns-Aftimos syndrome. The major clinical anomalies are striking facial dysmorphism (present in all cases) with hypertelorism, broad nose with large tip, congenital ptosis, ridged metopic suture, and highly arched eyebrows. Microcephaly may develop with time. Iris or retinal coloboma is present in many cases, as does sensorineural deafness. Cleft lip and palate, and hallux duplex may be present. Pachygyria with antero-posterior gradient is present in almost all cases. Progressive joint stiffness is observed in elder patients, although early muscular involvement with even congenital arthrogryposis may be present in some. Intellectual disability and epilepsy are variable and correlate with CNS anomalies. Facial dysmorphism appears to be the most reliable criteria to evoke BRWS.

C02.5

A comprehensive analysis of a cohort of Cornelia de Lange syndrome cases.

M. Ansari[1], *R. Aldridge*[1], *G. V. Poke*[2], *K. Williamson*[1], *T. Homfray*[3], *R. C. M. Hennekam*[4], *D. R. FitzPatrick*[1];

[1]*Institute of Genetics and Molecular Medicine, Edinburgh, United Kingdom,* [2]*South East of Scotland Clinical Genetic Service, Edinburgh, United Kingdom,* [3]*St George's Healthcare NHS Trust, London, United Kingdom,* [4]*University of Amsterdam, Amsterdam, Netherlands.*

Cornelia de Lange syndrome (CdLS) is a multiple congenital malformation syndrome characterised by mild to severe developmental delay, growth retardation, limb abnormalities and prominent facial features. Approximately 65% of typical cases carry *de novo* heterozygous loss-of-function mutations in genes involved in sister chromatid cohesion; *NIPBL*, *SMC1A*, *HDAC8*, *RAD21* and *SMC3*. We developed an AmpliSeq PCR assay providing a template for IonTorrent sequencing to enable rapid parallel sequencing of all known CdLS genes. Of the 158 CdLS and CdLS-like cases in the MRC HGU CdLS Expanded Phenotype Cohort, 148 have been screened revealing 34, 6, 3 and 1 with mutations in *NIPBL*, *SMC1A*, *HDAC8* and *SMC3* respectively. In one male case a mosaic *SMC1A* mutation was detected at significantly different levels in two separate DNA samples, 53% and 10%. Array-CGH was performed on 104/148 cases and in two cases this identified plausible novel candidate genes for CdLS, *ESPL1* and *CDK11A/B*. DNA from six mutation-negative cases was then used for exome sequencing. In one case a *NIPBL* mosaic nonsense mutation was identified at 15% of reads in a patient with typical CdLS. In a second case a heterozygous frameshift in *ANKRD11* was identified in a patient with a CdLS-like phenotype. These data confirm *NIPBL* as the most commonly detectable cause of CdLS even in a cohort with broad ascertainment criteria. Genetic heterogeneity is marked within CdLS and CdLS-like cases and molecular analysis is showing significant phenotypic overlap with other dysmorphic syndromes such as KBG.

Treacher-Collins/Franceschetti syndrome (TCFS, MIM 154500) is a disorder of craniofacial development belonging to the heterogeneous group of mandibulofacial dysostosis. TCFS is characterized by bilateral mandibular and malar hypoplasia, down slanted palpebral fissures, and microtia. To date 3 genes have been identified in TCFS namely TCOF1, POLR1D and POLR1C. Here we report a clinical and extensive molecular study in a series of 135 TCFS patients. All the patients were screened for TCOF1. In absence of mutation, POLR1D and POLR1C were studied and array-CGH as well as EFTUD2 screening was performed in the remaining negative patients. We have analysed the molecular results from this series in two subsets, namely typical and atypical TCFS, based on clinical features. In typical TCFS, we identified 79% of patients with a molecular anomaly in TCOF1, 6% in POLR1D and 0% in POLR1C. Deletion, nonsense, duplication/insertion, splice site, missense, indels mutations were found respectively in 43 (51%), 17 (20%), 10 (12%), 6 (7%), 3 (3.5%) and 2 (3%) patients. Among the atypical patients (with intellectual disability or microcephaly), we identified 2 patients with a mutation in EFTUD2, and 2 patients with a 5q32 deletion encompassing TCOF1 and CAMK2A, but no mutation in TCOF1, POLR1D or POLR1C.
Phenotype/genotype correlations were investigated for 20 clinical features including choanal atresia, cleft palate and hearing loss. We also compared the type of mutation in TCOF1 and its localization in the gene, in an attempt to associate degrees of severity or peculiar clinical features to a specific part of TCOF1.

Highly multiplexed targeted single-nucleotide polymorphism (SNP) amplification and sequencing as a method for identifying fetal chromosomal disorders from maternal cell-free DNA

B. Zimmermann[1], *M. Banjevic*[1], *M. Hill*[1], *P. Lacroute*[1], *M. Dodd*[1], *S. Sigurjonsson*[1], *P. Lau*[1], *D. Prosen*[1], *N. Chopra*[1], *A. Ryan*[1], *M. Hall*[1], *S. McAdoo*[1], *Z. Demko*[1], *B. Levy*[2], *M. Rabinowitz*[1];

[1]*Research and Development, Natera Inc., San Carlos, CA, United States,* [2]*Department of Pathology and Cell Biology, Columbia University, New York, NJ, United States.*

Most multiplex PCR reports describe at most 100-200 assays in a single reaction, as increasing probe number increases probe-probe interactions. This is problematic when sequencing amplified DNA, as resulting uninformative reads are costly. We previously reported multiplexing 11,000 single-nucleotide polymorphisms (SNPs); because increasing analyzed heterozygous SNPs increases test power, we expanded this to 19,488 SNPs, with >98% of sequence reads mapping to targeted regions. This massively multiplexed PCR assay targets SNPs to accurately determine fetal chromosomal copy number from cell-free DNA (cfDNA). This massively multiplexed PCR assay targets single-nucleotide polymorphisms (SNPs) to non-invasively detect fetal chromosomal copy number from cfDNA. As part of an institutional review board-approved study to validate our Next-generation Aneuploidy Test Using SNPs (NATUS) algorithm, cfDNA was isolated from maternal plasma and subjected to a multi-stage, multiplex PCR amplification at Natera's laboratory. Specifically, primers were designed using an informatics-based approach, minimizing primer-primer interactions. Targets included highly heterozygous SNPs from chromosomes 13, 18, 21, X, and Y. Cell-free and genomic DNA samples were pre-amplified for 15 cycles using PCR with 19,488 target-specific assays in a single reaction. An aliquot was transferred to a second 15-cycle PCR reaction. Finally, a 12-cycle PCR reaction added barcoded tags, and amplicons were sequenced using an Illumina HiSeq 2000. This approach accurately detected fetal chromosomal copy number at all five targeted chromosomes from cfDNA isolated from maternal plasma. By targeting SNPs, this approach identifies parental origin of fetal chromosomes and uniparental disomy, and will allow detection of triploidy, microdeletions/microduplications, and haplotype reconstruction.

Recent advances in non-invasive prenatal diagnosis show that massively parallel sequencing (MPS) of maternal plasma DNA allows accurate detection of common foetal aneuploidies. Here, we describe the results of a collaborative clinical study with the aim to validate the diagnostic accuracy of our non-invasive protocol based on MPS for detecting common autosomal aneuploidies and first clinical application experiences.

In the study maternal blood samples were collected from 522 pregnant women with risk for aneuploidies. Extracted cell-free plasma DNA was analysed using Illumina sequencing platform HiSeq2000 in a multiplexed fashion. Fetal aneuploidies were identified using a Median Absolut Deviation based z-score equation (DAP.21). After unblinding study data, a new bioinformatics algorithm based on GC normalization (DAP.plus) was applied. Results of MPS based technique were compared with those from invasive procedures. 40/41 samples were correctly classified as trisomy 21-positive (sensitivity: 97,6 %; one-sided confidence interval: 88.9 %) and 427/427 samples were correctly classified as trisomy 21-negative (specificity: 100%; one-sided confidence interval: 99.3%). Furthermore, 5/5 T13 cases and 8/8 T18 cases were correctly identified using DAP.plus. The overall detection rate of trisomies 13, 18 and 21 is 98.1% (53/54).

Due to the high accuracy, our DAP.plus algorithm allows detection of common autosomal trisomies and has the potential to decrease the use of invasive procedures. The test is especially suitable for women at risk in addition to first trimester screening to reduce the false-postive-rate. However, future clinical studies are required to validate MPS for the detection further fetal chromosomal abnormalities and fetal genomic imbalances.

C03.3

Clinical Performance Comparison of the Harmony(TM) Prenatal Test and First Trimester Combined Screening in a General Pregnancy Population

K. Nicolaides[1], *A. Syngelaki*[1], *G. Ashoor*[1], *T. Musci*[2], *E. Wang*[2], ***K. Song***[2];

[1]*King's College, London, United Kingdom,* [2]*Ariosa Diagnostics, San Jose, CA, United States.*

Objective

Compare clinical accuracy of Harmony™ Prenatal Test, a NIPT based on cfDNA analysis, to first- trimester combined screening using serum markers and nuchal-translucency (NT) measurement.

Methods

A general screening population of pregnant women presenting in their first trimester (11 weeks 0 days to 13 weeks 6 days) underwent screening for fetal trisomy 21 and 18 using free β-hCG, PAPP-A, and NT. Pregnancy outcome was determined by invasive testing or phenotypic evaluation of the newborn. An archived aliquot of plasma at the same time of serum screening was available which underwent blinded analysis with Harmony. Risk score results at various risk cut-offs from 1 in 100 (1%) to 1 in 1,000 (0.1%) from both test modalities were compared.

Results

Study population consisted of 1,949 pregnant women. Median maternal age was 31.8 years (IQR range: (27.7–35.4) Median gestational age was 12.6 weeks (IQR range: 12.3-13.0). 80 (4.1%) underwent invasive testing(CVS or amniocentesis). All eight fetal trisomy 21 and two fetal trisomy 18 cases were detected by both Harmony and first-trimester combined screening and confirmed by invasive testing. False-positive rate for Harmony was 0.1% (2 of 1,939) over all risk cut-off ranges whereas false-positive rate for first-trimester screening at risk cut-offs of 1/100, 1/300, and 1/1,000 was 2.8%, 6.7%, and 18.4% respectively.

Conclusions

Harmony Prenatal Test demonstrates a reduction in false-positive test results compared to first- trimester combined screening in a general pregnancy population. Use of NIPT as a first-line test for aneuploidy screening could reduce maternal anxiety and invasive procedures.

C03.4

Comprehensive Chromosome Screening in PGD and PGS - Ethical Challenges

K. Hens*, W. Dondorp, G. de Wert;*

Maastricht University, Maastricht, Netherlands.

Microarray technology allows for comprehensive screening of chromosomes of in vitro embryos. Such screening can give information about the health status of the potential future child revealing chromosomal abnormalities leading to conditions with variable prognosis, such as sex chromosome aneuploidies.

Ethical questions regarding selection and transfer of embryos are often tackled using different arguments that do not necessarily yield the same answer. Arguments related to the welfare of the potential child try to set a minimum threshold, such as the requirement to avoid serious harm. The principle of procreative beneficence states that couples have the duty to select the embryo with the best chances to lead a healthy life. In assisted reproduction, professionals are actively involved in the creation of the embryo, and are considered by some to be co-responsible for the outcome of the procedure and the welfare of the potential child. A parental duty may be interpreted as a duty to select the best embryo, but also as a duty (or a right) to accept children as they are. The principle of procreative liberty as stated by John Robertson dictates that prospective parents have the right to choose the offspring they want, even if this includes having a child with a chromosomal abnormality. Conflicts between professionals and couples can become apparent when a decision whether to transfer an embryo with a chromosomal abnormality needs to be taken. This paper tackles these potential conflicts assessing the different normative frameworks and suggests how and which decisions are ethically sound.

C03.5

The challenge of preconceptional, preimplantation, and prenatal genetic diagnoses of mitochondrial DNA disorders

s. monnot[1], *N. Gigarel*[1], *P. Vachin*[1], *E. Herzog*[2], *P. Burlet*[1], *N. Frydman*[3], *A. Benachi*[3], *G. Chalouhi*[1], *Y. Ville*[1], *R. Frydman*[1], *A. Lebre*[1], *A. Rotig*[4], *D. C. Samuels*[5], *C. Elie*[1], *A. Munnich*[1], *J. Bonnefont*[1], *J. Steffann*[1];

[1]*hopital necker, paris, France,* [2]*inserm U781, hôpital antoine béclère, Clamart, paris, France,* [3]*hopital antoine beclere, clamart, France,* [4]*inserm U781, paris, France,* [5]*Vanderbilt university medical center, nashville, TN, United States.*

Mitochondrial DNA (mtDNA) mutations cause a wide range of serious genetic diseases with no efficient therapy and high transmission risk, due to their maternal inheritance. Thus, "at risk" couples often ask for preconceptional (PCD), preimplantation (PGD) or prenatal diagnosis (PND). All these procedures are based on mutant load assessment in polar bodies (PCD), blastomeres (PGD), or fetal tissues (PND).

Here we report our 10-year experience in PCD, PGD and PND for mtDNA mutations in MT-ATP6 (m.8993T>G, m.9185T>C, NARP/ Leigh), MT-ND3 (m.10197G>A), MT-ND4 (m.14459G>A), MT-TL1 (m.3243A>G, MELAS), and MT-TK (m.8344A>G, MERRF). Mutant loads were quantified in 46 polar bodies, 19 oocytes, 52 preimplantation embryos, 35 fetuses, and 10 whole placentas from carrier females.

PCD was not a relevant approach, due to common mutant load discrepancies between first polar bodies and their counterparts. Conversely, mutant loads

were constantly stable among blastomeres from 42 embryos, making PGD an appropriate procedure. Mutant loads were stable across various tissues including amniocytes in 9 fetuses. However, intra-placental mutant load variations up to 55% were found. Such results preclude the use of chorionic villous sampling for PND. No temporal variation of mutant load was observed throughout pregnancy (21 fetuses). These data support analysis of a single amniocyte sample as the best PND approach.
Finally, 22 children were born from PGD/PND procedures and are healthy with a 4 months - 12 years follow-up. Preimplantation and prenatal heteroplasmy assessments are thus valuable tools to prevent the recurrence of the disease in families where a mtDNA mutation segregates.

C03.6

Exome sequencing of 27 trios to identify genetic causes of fetal abnormalities

K. J. Carss[1], *S. Hillman*[2], *E. Maher*[2], *P. Vijayarangakannan*[1], *D. Stemple*[1], *M. Kilby*[2], *M. Hurles*[1];
[1]*Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom,* [2]*Birmingham Women's Hospital, Birmingham, United Kingdom.*

Fetal abnormalities, as revealed by ultrasound, are a relatively common occurrence and the cause is often genetic. The method used to investigate these cases is usually a combination of karyotyping and aCGH, which in many cases does not yield a diagnosis. We propose that exome sequencing of trios in such cases may substantially increase the diagnostic rate, which will improve understanding of the biological basis of abnormal development, and inform the reproductive decisions of affected families.
Therefore, we have exome sequenced a cohort of 27 fetuses with diverse structural abnormalities including cardiac, musculoskeletal and nervous system defects, along with their parents. Additionally, we have performed aCGH on a subset of this cohort. We have identified rare functional SNPs, indels and CNVs, a subset of which are highly likely to be causal, on the basis of prior knowledge of candidate gene function. These include a de novo SNP in FGFR3 in a fetus with features of thanatophoric dysplasia, and a de novo 16.8 kb deletion that includes most of the gene OFD1 in a female fetus with ventriculomegaly and agenesis of the corpus callosum.
Thus far, our data suggest that exome sequencing trios may increase the diagnostic rate in fetuses with structural abnormalities over that achieved by aCGH alone. Further work will include expanding this cohort and functionally validating a subset of our candidate genes using animal models. This is, to our knowledge, the largest such cohort of structurally abnormal fetuses to have been exome sequenced.

C04.1

Mutations in SMARCE1 cause a novel disorder of multiple spinal meningiomas

W. G. Newman[1], *M. J. Smith*[2], *J. O'Sullivan*[2], *S. S. Bhaskar*[2], *K. D. Hadfield*[2], *G. Poke*[3], *J. Caird*[4], *S. Sharif*[5], *D. Eccles*[6], *D. Fitzpatrick*[7], *D. Rawluk*[4], *D. DuPlessis*[8], *D. G. Evans*[2];
[1]*Genetic Medicine, University of Manchester, Manchester, United Kingdom,* [2]*University of Manchester, Manchester, United Kingdom,* [3]*South East Scotland Genetic Service, Western General Hospital, Edinburgh, United Kingdom,* [4]*Department of Neurosurgery, Beaumont Hospital, Dublin, Ireland,* [5]*Department of Clinical Genetics, West Midlands Regional Genetics Unit,, Birmingham, United Kingdom,* [6]*University of Southampton, Southampton, United Kingdom,* [7]*MRC Human Genetics Unit MRC IGMM, University of Edinburgh, Edinburgh, United Kingdom,* [8]*Department of Cellular Pathology & Greater Manchester Neurosciences Centre, Salford Royal Hospitals NHS Foundation Trust, Salford, United Kingdom.*

Meningiomas comprise one third of all primary central nervous system tumours in adults. When they occur at multiple sites or in multiple family members, they are usually associated with neurofibromatosis type 2 (NF2) disease or familial schwannomatosis. In a subset of individuals, multiple meningioma disease occurs as an autosomal dominant manner without NF2 or SMARCB1 mutations. We sought to identify novel genes associated with meningioma development.
Method
We sequenced the exomes of three unrelated individuals with familial multiple spinal meningiomas without NF2 or SMARCB1 mutations.
Results
We identified two individuals with heterozygous novel loss of function mutations in the SWI/SNF chromatin remodelling complex subunit, SMARCE1. Sequencing of SMARCE1 in six additional individuals with spinal meningiomas identified two further novel heterozygous loss of function mutations. Tumours from individuals with SMARCE1 mutations were of clear cell histological subtype and all demonstrated loss of SMARCE1 protein consistent with a tumour suppressor mechanism.
Conclusion
Our findings define multiple spinal meningioma disease as a novel discrete entity and establish the key role of the SWI/SNF complex in the pathogenesis of both meningiomas and tumours with clear cell histology.

C04.2

Mosaic *PPM1D* mutations are associated with predisposition to breast and ovarian cancer

K. M. Snape[1], *E. Ruark*[1], *P. Humburg*[2], *T. Breast Ovarian Cancer Susceptibility Collaboration*[3], *T. Wellcome Trust Case Control Consortium*[3], *C. Turnbull*[1], *J. Reis-Filho*[1], *A. Ashworth*[1], *A. Antoniou*[4], *C. J. Lord*[1], *P. Donnelly*[5], *N. Rahman*[1];
[1]*Institute of Cancer Research, Sutton, United Kingdom,* [2]*The wellcome Trust Centre for Human Genetics, Oxford, United Kingdom,* [3]*Multiple, Multiple, United Kingdom,* [4]*University of Cambridge, Cambridge, United Kingdom,* [5]*The Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom.*

Breast and ovarian cancer are exemplars of the rare variant - common disease hypothesis, with the identification of rare mutations in the DNA repair genes *BRCA1, BRCA2, ATM, BRIP1, CHEK2, PALB2, RAD51C* and *RAD51D* conferring susceptibility to one, or both, diseases. By undertaking targeted resequencing of 507 genes implicated in DNA repair pathways in 1150 women with breast +/- ovarian cancer, and a large scale replication case-control experiment in 13,642 individuals, we have shown that rare protein truncating variants (PTVs) in the p53-inducible protein phosphatase *PPM1D* are associated with both breast and ovarian cancer. We identified *PPM1D* mutations in 25/7781 cases vs 1/5861 controls; (P=1.12x10-5), including 18 mutations in 6,912 individuals with breast cancer; (P = 2.42x10-4) and 12 mutations in 1,121 individuals with ovarian cancer; (P = 3.10x10-9). The *PPM1D* PTVs cluster within a 370bp region of the final exon of the gene, and are predicted to avoid nonsense mediated decay, resulting in a truncated protein product. Functional studies show that mutant PPM1D isoforms demonstrate enhanced suppression of p53 in response to ionising radiation, suggesting a gain-of-function mechanism of action. Deep resequencing of a subset of samples confirmed that the PTVs were mosaic in lymphocyte DNA and intriguingly absent from tumour tissue, suggesting a novel mechanism of cancer association, which is genetic but not hereditary. This data has clinical implications for the detection and management of women with susceptibility to breast and ovarian cancer, and provides new insights into the role of rare and mosaic variants in common disease.

The development of sporadic early-onset cancers, in patients without detectable germline mutations within known genes involved in Mendelian cancer predisposition, might be explained by rare de novo mutations under strong negative selection. We considered, as a paradigm, early-onset epithelial ovarian cancer and performed comparative index case-parents exome sequencing in a patient who presented, at 21 years of age, large bilateral serous ovarian adenocarcinoma. We identified a heterozygous de novo mutation (c.1157A>G p.Asn386Ser) within the INHBA gene encoding the betaA subunit of inhibins/activins, which are members of the TGF-beta superfa-

mily secreted by granulosa cells and play a key role in ovarian development. Functional analyses performed in vitro showed that the INHBA p.Asn386Ser mutation results in an increase of inhibin A and a concomitant decrease of activin A and, therefore, favours dimerisation of the inhibin betaA-subunit with the inhibin alpha-subunit. Screening for inhibin mutations in 19 other cases of early-onset ovarian epithelial tumours led us to identify within the INHA gene encoding the inhibin alpha-subunit, a germline mutation (c.179G>T, p.Arg60Leu) affecting the secondary furin cleavage site of the inhibin alpha -prodomain and functional analysis showed that this mutation is disruptive for both inhibin A and B biosynthesis. These results suggest that germline mutations of inhibins might be oncogenic in ovaries by altering the inhibin/activin ratio and, therefore, the crosstalk between granulosa and epithelial cells.

Background: Parkinson's disease (PD), a neurodegenerative disease of losing melanin-positive dopaminergic neurons, is epidemiologically linked to cutaneous melanoma (CM). *PARKIN* (*PARK2*), an important genetic predisposition to PD encoding an E3 ubiquitin ligase involved in cyclin E degradation, is also a tumor suppressor gene. We investigated the role of *PARK2* on melanoma susceptibility and oncogenesis.

Patients and methods: We recruited 500 CM patients (familial, multiple, or <25 year), 320 healthy controls, 31 tumors, and 24 melanoma cell lines. Point mutations and copy number variations (CNVs) were investigated by sequencing and MLPA, qPCR, and CGH, respectively. *PARK2* abnormalities were collected for 2060 additional controls from ten publications. PARKIN expression and cell proliferation in melanoma cell lines were also investigated.

Results: We identified 15 inactivated *PARK2* alleles leading to a truncated protein (2 splicing, 1 frameshift, and 12 exonic CNVs) in 16 CM patients (3.2%) and in 0.6% of controls (P<0.0001;OR=5.56[2.49-12.55]). *PARK2* CNVs were present in 60% of cell lines and in 50% of tumors, and LOH was detected in 50% of cell lines. PARKIN was absent in 90% of cell lines whereas present in melanocytes. Transfection of wild type *PARK2* cDNA markedly inhibits cell proliferation in three cell lines.

Conclusion: We point out a common genetic pathway that could explain the epidemiological association between PD and CM, by showing that *PARK2* inactivation plays an important role in melanoma predisposition and oncogenesis. This provides new insights in CM oncogenesis that could help targeted therapy design, and may have dermatological clinical implications in PD.

Loss of a Regulatory Element May Determine Endometrial Cancer Risk in *EPCAM* Deletion Carriers

R. M. de Voer, *E. Verwiel, M. Donna, E. van Wijk, L. Vreede, R. Freixas, K. Wu, I. Nagtegaal, N. Hoogerbrugge, A. Geurts van Kessel, M. Ligtenberg, R. Kuiper;*
Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Lynch syndrome is caused by germline mutations in the mismatch-repair genes *MLH1*, *MHS2*, *MSH6* and *PMS2*. Mutation carriers exhibit a high risk of developing colorectal cancer (CRC) and endometrial cancer (EC). We recently found that constitutional 3'end deletions of *EPCAM* cause epigenetic silencing of *MSH2* in *EPCAM*-expressing tissues, thus providing a new cause of Lynch syndrome[1]. *EPCAM* deletion carriers have a similar CRC risk as *MSH2* mutation carriers, but ECs were only observed in patients with deletions extending close to the *MSH2* promoter[2]. Therefore, we hypothesized that in endometrial cancer precursor cells *MSH2* inactivation is not caused by read through-mediated silencing, but by loss of a regulatory element. Indeed, a 5.5-kb region upstream of *MSH2*, shows a site with H3K4Me1 and H3K4Me2 in the hepatocellular carcinoma cell line HepG2, suggesting the presence of a regulatory element. We generated and tested luciferase reporter constructs containing segments of the 5.5-kb region in a panel of cancer cell lines. A fragment of 1.5-kb, located 4.8-kb upstream of *MSH2*, revealed enhancer activity in the CRC cell line HCT116. Currently we are studying this region in a zebrafish model for determining its cell type-specific regulatory role *in vivo*. Our data suggest that through *EPCAM* deletions that extend close to the *MSH2* promoter an enhancer element is lost. This loss may cause an increased risk for endometrial cancer in carriers of *EPCAM* deletions that extend close to the *MSH2* promoter.

Suppressor-tRNA Restores Functional E-Cadherin Expression in *Cdh1* Mutant Cancer Cells: A Potential Approach to Treat Hereditary Diffuse Gastric Cancer

R. Bordeira-Carriço[1], *D. Ferreira*[1], *D. Mateus*[1], *H. Pinheiro*[1], *A. Pêgo*[2,3], *R. Seruca*[1,4], *M. Santos*[5], *C. Oliveira*[1,4];

[1]*IPATIMUP - Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal,* [2]*INEB - Instituto de Engenharia Biomédica da Universidade do Porto, Porto, Portugal,* [3]*Faculty of Engineering of the University of Porto, Porto, Portugal,* [4]*Faculty of Medicine of the University of Porto, Porto, Portugal,* [5]*University of Aveiro, Aveiro, Portugal.*

Introduction: Hereditary Diffuse Gastric Cancer (HDGC) is a highly penetrant autosomal dominant disease caused by *CDH1* (E-cadherin encoding gene) germline mutations, often originating premature termination codons (PTC). HDGC arises at early age, with multifocal tumors frequently missdetected by endoscopy. Prophylactic gastrectomy is the only therapeutic approach for asymptomatic mutation carriers. We hypothesize that suppressor-tRNAs could replace PTCs by the correct aminoacid in *CDH1* nonsense-mutation carriers and delay cancer development.

Material and Methods: We established a cell line model expressing wild-type and nonsense mutant *CDH1* mini-genes (full-length cDNA enclosing a minimal intron before the last exon - CDH1_WT and CDH1_1003) to study *CDH1* truncating mutations and its reversion. A suppressor-tRNA was designed to recognize the nonsense codon in AGS, MDA-MB-231 and CHO cells line models. CDH1 mRNA expression was analysed by RT-PCR and protein expression by western blot, immunocytochemistry and flow citometry.

Results: CDH1_WT originates correctly spliced mRNA and full-length E-cadherin, correctly localized at the membrane, rescuing cell-adhesion and suppressing invasion, unlike CDH1_1003. Expression of a suppressor-tRNA rescued membranous and potentially functional E-cadherin expression in CDH1_1003 mutant cells to levels resembling those of CDH1_WT cells.

Conclusions: The *in vitro* recovery of membranous E-cadherin expression in cells expressing a nonsense mutation, through tRNA-nonsense suppression, may constitute the basis for a novel gene therapy aiming at reverting truncating mutations in cancer-associated syndromes.

Association studies identified BCL11A transcription factor as the master regulator of fetal hemoglobin (HbF) expression as well as a key modifier of both β-thalassemia and sickle cell anemia (SCA) phenotypes. Recently, we refined the association signal at this locus by GWAS on 5903 individuals from the SardiNIA project, integrating, with imputation procedure, DNA microarray data and low pass whole-genome sequencing of 2120 Sardinians. Our results revealed two independent SNPs within intron 2 of the BCL11A gene, leading the strongest haplotypic signals and fully accounting for the association observed at this locus. Given that intron 2 shows chromatin signatures of genomic elements with a potential regulatory activity, we carried out functional and expression analysis to asses the specific impact of associated variants in gene action. Preliminary luciferase reporter assays on erythroleukemia cell lines (K562, HEL) have shown a promoter/enhancer activity embedded in the regions encompassing two of them. Notably for one SNP, EMSA on human primary erythroid cells (BFUe) also detected a differential binding pattern showing developmental stage and allele specificity. Furthermore, RT-qPCR and allelic specific expression assays (ASE) conducted on BFUe cells derived from β-thalassemia patients suggest that the associated SNPs, might function as cis-acting regulatory variants, affecting its expression in a temporal and tissue specific manner. Overall our results support that genetic variants at intron 2 of BCL11A play a crucial role in modulating its function controlling HbF levels with consequent amelioration of β-thalassemia severity.

Understanding functional effects of genetic variants is one of the biggest challenges in human genomics. Towards this goal, we sequenced mRNA and small RNA from lymphoblastoid cell lines of 465 individuals from 5 populations of the 1000 Genomes Project. Population comparisons showed splicing rather than expression dominating continental differences (75-85% differentially splices genes EUR-ARF vs 6-40% EUR-EUR), putatively suggesting a special role of splicing in human adaptation. We found extremely widespread regulatory variation, with genetic variants associating to gene expression levels of 7825 genes, transcript structure of 639 genes, as well as expression of 60 miRNAs. Allele-specific transcription analysis allowed us to characterize rare regulatory effects and underlying genetic variants. Importantly, genome sequencing data combined with functional annotation of the genome allowed us to infer putative causal regulatory variants for 57-75% of eQTL genes. We apply this to predict causal variants for 91 disease-associated loci, and also characterize transcriptome effects of loss-of-function variants, thus linking our discoveries to genetic associations to human disease. Altogether, the integration of genome sequencing and functional genomics data in this study takes us towards understanding and predicting molecular genomic effects of causal functional variants in the human genome.

C05.3

Genetic regulation of lincRNA and protein-coding genes expression variation - similarities and differences

K. Popadin[1], *M. Gutierrez-Arcelus*[1], *T. Lappalainen*[1,2], *E. Dermitzakis*[1], *S. E. Antonarakis*[1];

[1]*Department of Genetic Medicine and Development, Geneva, Switzerland,* [2]*Department of Genetics, Stanford University School of Medicine, Stanford, CA, United States.*

We have investigated by RNA-seq the gene expression variation in the GenCord collection: three cell types (fibroblasts - F, lymphoblastoid cell lines - L and T-cells - T) from umbilical cord of 195 unrelated European individuals. We have observed expression of 392, 553 and 546 large intergenic non-coding RNA genes (lincRNAs) in F,L and T respectively. LincRNAs are lowly expressed, highly-tissue specific and located close to protein-coding genes involved in regulation of transcription. LincRNAs' gene size negatively correlates with expression level, as it is known for protein-coding genes, thus demonstrating similar evolutionary constraints between lincRNA and protein-coding genes. Among expressed lincRNAs we have found 54, 102 and 65 genes from F,L and T correspondingly with cis expression Quantitative Trait Loci (cis-eQTL). Comparison of regulation patterns of lincRNA and protein-coding genes has revealed two characteristic features of lincRNAs: (i) they have excess of cis-eQTLs and (ii) lincRNAs' eQTLs are located closer to transcription start sites (TSS). Our analysis of protein-coding genes has shown that both excess of cis-eQTLs and close location of cis-eQTLs to TSS are specific also for evolutionary young (primate-specific) protein-coding genes. We conclude that lincRNAs and young protein-coding genes have similar evolutionary landscape of regulation.

Recent advances in genome-wide profiling of transcription factor (TF) binding and histone modifications have identified specific chromatin signatures related to various classes of functional elements in different cell types.

However, their genetic basis and degree of variability across individuals remain largely unknown. We generated genome-wide enrichment profiles of TF binding, chromatin marks, and different measures of transcription in lymphoblastoid cell lines from two trios and 8 unrelated individuals sequenced in high depth as part of the 1000 Genomes project. Inter-individual variability of these phenotypes was quantified to understand both DNA sequence dependent and independent variation on transcription, TF binding, chromatin state, and their interplay in an allele-specific framework. Different organizational layers of the genome show abundant allelic effects and strong allelic coordination between layers, with the genetic control of this coordination acting primarily through transcription factor binding. Our findings support the notion of transcription factors being the primary determinants of gene expression programs, with the overall chromatin state reflecting, but not necessarily driving gene expression activity. We extended our analysis to 54 unrelated individuals for most assays to identify genetic effects affecting chromatin properties on a population level, and continue exploring the combinatorial patterns of all assays to further dissect the components of the general transcriptional state of the cells. This study will significantly improve our understanding of the biological landscape around regulatory and other functional elements of the genome, and provide better means to interpret the heritability and molecular basis of phenotypic diversity, such as disease susceptibility, in humans.

C05.5

Deciphering vertebrate regulatory grammar using high-throughput in vivo functional assays

*R. P. Smith[1,2], L. Taher[3,4], S. J. Riesenfeld[5], R. P. Patwardhan[6], I. Ovcharenko[3], K. S. Pollard[5,2,7], J. Shendure[6], **N. Ahituv**[1,2];*

[1]Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA, United States, [2]Institute for Human Genetics, University of California San Francisco, San Francisco, CA, United States, [3]National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD, United States, [4]Institute for Biostatistics and Informatics in Medicine and Ageing Research, University of Rostock, Rostock, Germany, [5]Gladstone Institutes, University of California San Francisco, San Francisco, CA, United States, [6]Department of Genome Sciences, University of Washington, Seattle, WA, United States, [7]Division of Biostatistics, University of California San Francisco, San Francisco, CA, United States.

Despite continual progress in the cataloging of vertebrate regulatory elements, little is known about the grammatical rules that govern their intensity and spatio-temporal extent. Deciphering these rules will enable high-resolution mapping of regulatory elements, accurate interpretation of nucleotide variation within them, and the design of sequences that can deliver molecules for therapeutic purposes in a spatio-temporal manner. Here, we describe two novel approaches that we have developed to systematically improve our understanding of regulatory grammar. In the first approach, mathematical theory and computational methods were developed to construct an ultra-compact collection of DNA oligomers encompassing all possible 6bp sequences, which were screened in 15 tissues and two time points using zebrafish transgenesis. Twenty-seven (from 184) of these constructs produced consistent expression patterns, many of which were tissue-specific and were further used to design robust, tissue-specific enhancers. Using a second approach, we systematically decoded the rules governing TFBS arrangement and combination by testing ~5,000 synthetically designed sequences using a massively parallel reporter assay in the mouse liver. We find that certain transcription factors act as direct drivers of gene expression in homotypic clusters, independent of spacing, whereas others function only synergistically. Heterotypic enhancers are stronger than their homotypic analogs, and favor specific TFBS combinations, mimicking putative native enhancers. Finally, exhaustive testing of binding site permutations supported a model with flexibility in binding site order. This work provides a unique catalog of tissue-specific synthetic enhancers as well as a massively parallel view of the basic principles of regulatory function in vivo.

Many disease-associated variants affect gene expression levels (expression quantitative trait loci, eQTLs). Expression profiling using next generation sequencing (NGS) technology is very powerful to detect these eQTLs.
Here we analyzed 94 total blood samples from healthy volunteers with DeepSAGE to gain specific insight how genetic variants affect the expression of genes and and lengths of 3'-untranslated regions (3'-UTRs). We detected previously unknown cis-eQTL effects for GWAS hits in disease- and physiology-associated traits. Apart from cis-eQTLs that are typically well identifiable using microarrays or RNA-seq, DeepSAGE revealed many cis-eQTLs for antisense and other non-coding transcripts, often in genomic regions containing retrotransposon-derived elements. Furthermore, we identified and confirmed SNPs that affect the usage of alternative polyadenylation sites, thereby potentially influencing the stability of mRNAs.
We subsequently combined the power of RNA-seq with DeepSAGE by performing a meta-analysis of three datasets, resulting in the identification of a substantially increased number of cis-eQTLs.
Our results indicate that DeepSAGE data is useful for eQTL mapping of known and unknown transcripts, and identification of SNPs that affect alternative polyadenylation. Because of the inherent differences between DeepSAGE and RNA-seq, the complementary integrative approach that we describe here helps to gain better insight in the molecular consequences of many disease-associated variants.

C06.1

The disease mechanisms of FSHD1 and FSHD2 converge at the level of somatic expression of DUX4

***S. M. van der Maarel**[1], R. Lemmers[1], B. Bakker[1], R. Tawil[2], S. Sacconi[3], D. Miller[4], S. Tapscott[5];*

[1]Leiden University Medical Center, Leiden, Netherlands, [2]University of Rochester Medical Center, Rochester, NY, United States, [3]Nice University Hospital, Nice, France, [4]University of Washington, Seattle, WA, United States, [5]Fred Hutchinson Cancer Research Center, Seattle, WA, United States.

Facioscapulohumeral dystrophy (FSHD) is caused by decreased epigenetic suppression of the D4Z4 repeat array on chromosome 4 resulting in expression of the D4Z4-encoded *DUX4* gene in skeletal muscle.
Two variants of chromosome 4 exist of which only one is permissive to *DUX4* expression due to the presence of a polymorphic *DUX4* polyadenylation signal. In most patients, loss of epigenetic suppression of *DUX4* is caused by contraction of the D4Z4 array (FSHD1) on a permissive allele and is inherited as a dominant trait. However, in some patients the decrease in epigenetic suppression occurs on normal-sized arrays (FSHD2) and shows a complex inheritance pattern. We discovered that mutations in the chromatin modifier SMCHD1 on chromosome 18 segregate with genome-wide D4Z4 CpG hypomethylation in FSHD2 families. In FSHD2 patients the disease is thus caused by digenic inheritance of a SMCHD1 mutation and a normal-sized D4Z4 array permissive for *DUX4* expression. Currently, we have identified >50 *SMCHD1* mutations *SMCHD1* explaining 80% of FSHD2. The mutation spectrum provides new insights in the disease mechanism and we observed that *SMCHD1* mutations can also aggravate disease severity in FSHD1 families.
SMCHD1 is a chromatin modifier that binds directly to the D4Z4 repeat. In FSHD2 patients there is reduced binding of SMCHD1 to D4Z4 and knock down of SMCHD1 in normal myoblasts containing a permissive chromosome 4 leads to the activation of *DUX4*. Our data thus suggest FSHD1 that the disease mechanisms of FSHD1 and FSHD2 converge at the level of D4Z4 chromatin decondensation and somatic *DUX4* expression.

F-actin bundling plastin 3 (PLS3) is a fully protective modifier of the neuromuscular disease spinal muscular atrophy (SMA), the most common genetic cause of infant death. The generation of a conditional PLS3 over-expressing mouse and its breeding into an SMA background allowed us to decipher the exact biological mechanism underlying PLS3-mediated SMA protection. We show that PLS3 is a key regulator that restores main processes depending on actin dynamics in SMA motor neurons (MN). MN soma size significantly increased and a higher number of afferent proprioceptive inputs were counted in SMAPLS3 compared to SMA mice. PLS3 increased presynaptic F-actin amount, rescued synaptic vesicle and active zones content, restored the organization of readily releasable pool vesicles and increased quantal content at the neuromuscular junctions (NMJs). Most remarkably, stabilized axons by PLS3 over-expression delayed axon pruning, counteracting poor axonal connectivity at SMA NMJs. These findings together with the observation of increased endplate and muscle fiber size upon MN-specific PLS3 overexpression suggest that PLS3 significantly improves neurotransmission. Indeed, ubiquitous over-expression improves survival and motor function in SMA mice. As PLS3 seems to act independently of Smn, PLS3 might be a potential therapeutic target not only in SMA but also other MN diseases.

Distal arthrogryposis (DA) is a subgroup of arthrogryposis multiplex congenita (AMC) characterized by multiple congenital joint limitations. Using a pangenomic approach in 2 consanguineous families with DA, we identified a common morbid locus that mapped to chromosome 2q37 and harbored the Endothelin Converting Enzyme Like 1 (*ECEL1*) gene. We screened a panel of 20 DA families and identified 7 different mutations in six families. All mutations resulted either in the absence of the protein or in the synthesis of a non-functional protein, suggesting a loss of function mechanism. *ECEL1* encodes a neuronal endopeptidase expressed in the peripheral (PNS) and central nervous system during fetal life and plays a major role in intramuscular branching of motoneurons in skeletal muscle.Patients presented with a homogeneous phenotype characterized by limited knee flexion, flexed third to fifth fingers and relatively spared index finger, severe muscle atrophy in lower limbs and tongue. Muscle imaging showed a recognizable pattern of the thigh muscles. No dysfunction of the neuromuscular transmission was evidenced.On the whole, clinical features point towards a disorder involving the PNS. A developmental dysfunction is suggested by the predominantly prenatal expression of *ECEL1*, the non-progressive course of the disease and K.O. mouse data.

In skeletal muscle, Ca2+ is mainly stored in the sarcoplasmic reticulum (SR). Ca2+ is released to the cytoplasm upon stimulation, where it triggers muscle contraction and acts as a second messenger controlling growth and differentiation. Ca2+ stores are refilled through a process called store-operated Ca2+ entry (SOCE). Stromal interaction molecule 1 (STIM1) is the main Ca2+ sensor in the endoplasmic reticulum. We identified STIM1 mutations as the genetic cause of tubular aggregate myopathy (TAM), characterized by regular arrays of membrane tubules on muscle biopsies. All nine heterozygous mutations (including 5 novel) were found in the highly conserved intraluminal EF-hands, sensing and binding Ca2+. Upon Ca2+ store depletion, wild-type STIM1 oligomerizes and thereby triggers extracellular Ca2+ entry. In contrast, myoblasts transfected with the mutant constructs displayed constitutive STIM1 clustering, indicating that Ca2+ sensing was lost. We investigated the pathological mechanism underlying the disease and monitored the calcium response of patient myoblasts to SOCE. We found a significantly higher basal Ca2+ level in patient cells as compared to the control. Addition of high [Ca2+] medium induced a sudden and massive Ca2+ influx in the patient myoblasts, as compared to low gradual increase in control cell lines. These data demonstrate that dominant STIM1 mutations induce a constitutive activation of the Ca2+ entry channels in muscle cells. Recessive loss-of-function mutations in STIM1 have been associated with severe immune deficiency, demonstrating that a tight regulation of STIM1-dependent SOCE plays an essential role in T-cell activation as well as in normal skeletal muscle structure and function.

Myotonic dystrophy type 1 (DM1) is a complex multisystemic disorder, which displays multiple debilitating neurological manifestations. Despite recent progress in the understanding of the molecular pathogenesis of DM1 in skeletal muscle and heart, the pathways affected in the central nervous system (CNS) require further investigation.

In our studies we have used DMSXL transgenic mice expressing large CTG trinucleotide repeats within the human DM1 locus, notably in the CNS. These mice recreate molecular features of RNA toxicity in brain, such as RNA foci accumulation and dysregulation of alternative splicing, in association with the sequestration of MBNL splicing regulators and upregulation of CELF proteins.

Detailed phenotyping revealed relevant cognitive deficits and behavioural abnormalities, altered short-term synaptic plasticity, as well as changes in neurochemical levels. To decipher the molecular bases behind these phenotypes, a global proteomics approach revealed RAB3A upregulation and abnormal synapsin 1 hyperphosphorylation in the CNS of transgenic mice. These abnormalities were confirmed in transfected cells and validated in post-mortem DM1 brains. Using complimentary DM1 mouse models, we showed that RAB3A upregulation results from the sequestration of MBNL1 in RNA foci, while synapsin 1 hyperphosphorylation is mediated by the upregulation of CELF proteins. Interestingly, synaptic protein defects were associated with altered spontaneous neurosecretion in cell culture and are likely to contribute to the electrophysiological and behavioural deficits of DM1 transgenic mice.

The novel connection between physiological phenotypes and synaptic protein deregulation reveals synaptic dysfunction in DM1 brain pathology.

Nanoparticles as delivery systems for antisense oligoribonucleotides: biodistribution studies and definition of the release kinetic in intraperitoneally and orally treated mdx mice

*M. Falzarano[1], C. Passarelli[1], K. Sparnacci[2], M. Laus[2], P. Bonaldo[3], P. Braghetta[3], J. vanDeutekom[4], **A. Ferlini**[1];*
[1]Department of Medical Sciences, Ferrara, Italy, [2]Environmental and Life Sciences INSTM, University of Eastern Piedmont, Alessandria, Italy, [3]Histology, Microbiology, and Medical Biotechnology, University of Padua, Padua, Italy, [4]Prosensa Therapeutics, Leiden, Netherlands.

Antisense-mediated exon skipping is a very promising therapeutic option for Duchenne muscular dystrophy and other diseases susceptible of splicing correction. We have tested different types of polymeric cationic core-shell nanoparticles (NPs) for delivering 2-O-methyl-phosphorothioate antisense oligoribonucleotides (AONs), in mdx mice. Both T1 and ZM2 NP bind and convey AONs: intraperitoneal (IP) injections of low doses (52.5mg/kg) of NP-AON complex restored dystrophin protein synthesis in skeletal and cardiac muscles, allowing protein localization in up to 40% of muscle fibers with skipping level up to 20%. We have administered NP-AON complexes orally and tested in vivo (mdx) the tissue biodistribution and elimination timing of NPs by Odyssey, using an infrared dye conjugated ZM2 NP. The NP-AON formulations passes the gastric barrier and induce a limited dystrophin rescue in the intestinal smooth muscles as well as in the diaphragm. WE have also identified a novel NP (ZM5) able to pass the intestinal barrier. In order to get insight about the release kinetic of the AON from NPs, we have performed ELISA assay to dose the antisense in the all mice muscles , both IP and oral treated. We demonstrated that AON are rapidly released from NPs (with no depot effect) but those AON reaching tissues and exerting the functional effect are well protected from degradation. Defining the kinetic of NP-AON complexes is crucial in order to further proceed with other NP studies following non invasive administration routes, as oral and skin adsorption.

Mitochondrial disorders present as a genetically and clinically extremely heterogeneous disease. Up to now 250 mitochondrial genes have been identified, whereas more than 1000 genes are predicted to encode for mitochondrial proteins. To identify disease causing mutations, we applied exome sequencing in combination with stepwise filtering of gene variants and functional complementation for 120 unrelated individuals with juvenile-onset mitochondrial disorders without pathogenic variants in the mtDNA. We were able to detect mutations in known disease genes in 40% of cases, whereas in 10% novel disease causing genes were identified. The list of such newly identified genes increases steadily: most recently we identified MGME1 to be the first exonuclease involved in mitochondrial replication (Kornblum et al., Nat. Genet. 2013). Most notably, it is also possible to detect mutations in genes which are not predicted candidates for being a mitochondrial protein but which cause a clear mitochondriopathy phenotype e.g. mutations in the riboflavin transporter encoding gene SLC52A2. The challenge now is, apart from improving sequencing technology, to annotate variants in non-coding regions, to identify indels and copy number variants, as well as considering how to tackle diseases caused by di- or oligogenic mutations exerting a synergistic effect. Till then, each gene newly identified by exome sequencing holds the promise for new treatment options, as for example riboflavin supplementation in the case of mutations in SLC52A2, and helps to shed more light on mitochondrial physiology.

Congenital Disorders of Glycosylation (CDG) are a group of rare metabolic diseases, caused by impaired protein or lipid glycosylation. To date, over 50 distinct disorders have been described. In the last two years, the discovery of new CDG genes has occurred faster than ever thanks to massive parallel sequencing. We identified MAN1B1 as the culprit gene in a patient with CDG-II by means of exome sequencing. Subsequently, six additional cases were identified from a cohort of unsolved CDG-II. All patients presented intellectual disability, facial dysmorphism and truncal obesity. Thus, we describe MAN1B1 deficiency as a relatively frequent cause of CDG.
MAN1B1 is believed to be an ER resident α(1,2)-mannosidase acting as a key enzyme in the glycoprotein quality control system. It targets misfolded glycoproteins for ER associated degradation (ERAD) by cleaving a terminal mannose residue from the asparagine-linked Man9GlcNAc2, forming Man8GlcNAc2 isomer B. Biochemical analysis indeed confirmed a delay in the trimming of Man9GlcNAc2 to Man8GlcNAc2 in patients' cells. Interestingly, Golgi morphology was altered in all patients, with marked dilation and fragmentation. We infer from this observation that part of the phenotype is linked to Golgi disruption. Moreover, we showed that the endogenous MAN1B1 is localized to the Golgi apparatus, instead of the ER where quality control is supposed to occur. Hence, our results challenge the current view on glycoprotein quality control, even though more work is needed to propose a new role for MAN1B1 and to explain the pathophysiology.

Mitochondrial-dependent programmed cell death (PCD), plays an essential homoeostatic role, by selecting bioenergetically proficient cells suitable for normal tissue and organ development. Despite intensive investigation, the impact of this crucial process in human diseases remains poorly understood. In particular, the link between apoptosis and mitochondrial disorders, i.e. primary defects of oxidative phosphorylation, has not been persuasively demonstrated.
We demonstrated that activation of non-canonical mitochondrial-depen-

dent PCD causes the Microphthalmia with Linear Skin lesions (MLS), a developmental disorder associated to mutations in HCCS, encoding the Holo-Cytochrome c-type synthase, which incorporates the heme-c moieties in the mitochondrial respiratory chain (MRC). By generating a Medakafish model that recapitulates the MLS phenotype, we demonstrate that hccs downregulation, induced PCD in the central nervous system (CNS) via an apoptosome-independent caspase-9 activation triggered by MRC impairment and overproduction of reactive oxygen species.

We then screened MRC-related genes in HCCS-negative MLS patients, and found deleterious de novo mutations in two simplex cases and a nonsense mutation, which segregates with the disease in a familial case, in COX7B encoding a poorly characterized subunit of Cytochrome c oxidase (COX), the MRC complex IV. We demonstrated that COX7B is indispensable for COX assembly, COX activity and mitochondrial respiration. Finally downregulation of cox7B in medaka resulted in microcephaly and microphthalmia that recapitulated the MLS phenotype and demonstrated an essential function of complex IV activity in vertebrate CNS development.

These data indicate an evolutionary conserved role for MRC in organogenesis and uncover a group of mitochondrial diseases hallmarked by an apoptosis-driven abnormal development.

The iron sulphur [Fe-S] proteins play an important role in redox reactions of the mitochondrial electron transport chain. In this study, we have identified two siblings from consanguineous parents, who died perinatally from a condition characterised by generalised hypotonia, respiratory insufficiency, anthrogryposis, microcephaly, congenital brain malformations and hyperglycinemia. Analysis of the catalytic activities of the mitochondrial respiratory complexes I and II indicated deficiency in skeletal muscle, suggestive of an inborn error in the mitochondrial iron-sulfur cluster (ISC) biosynthesis pathway. Homozygosity mapping revealed the *IBA57* gene, which is known to be involved in the biosynthesis of mitochondrial [4Fe-4S] proteins and present in the largest homozygous region on chromosome 1, as a candidate gene. Mutation analysis of *IBA57* identified a c.941 A>C transversion causing the aminoacid change p.Gln314Pro. Biochemical analysis of skeletal muscle and skin fibroblasts of affected individuals indicated severely decreased amounts of IBA57 and a decrease in various 4Fe-4S proteins and in proteins covalently linked to lipoic acid. IBA57 depleted HeLa cells reflected biochemical defects consistent with observations in patient derived cells. Defects could be rescued by the introduction of wildtype *IBA57* and partially by mutant *IBA57*. Further functional analysis revealed an increased sensitivity of mutant IBA57 to degradation via proteolysis. Our findings suggest that the mutation leads to functional impairment and degradation below physiologically critical levels, resulting in the condition observed in the patients. In conclusion, we have identified a novel metabolic disorder presenting with a lethal complex biochemical phenotype caused by defective assembly of the ISC protein, IBA57.

Exome sequencing Reveals Mutated NUBPL in Patients with Complex I Deficiency and a Distinct MRI Pattern

S. H. Kevelam[1], *R. J. Rodenburg*[2], *N. I. Wolf*[3], *P. Ferreira*[3], *R. J. Lunsing*[4], *L. G. Nijtmans*[2], *A. Mitchell*[5], *H. A. Arroyo*[6], *D. Rating*[7], *A. Vanderver*[8], *C. G. M. van Berkel*[1], *T. E. M. Abbink*[1], *P. Heutink*[1], *M. S. van der Knaap*[1];

There are many rare childhood leukoencephalopathies and till this day a high percentage of cases remain without a specific diagnosis. We used MRI-pattern recognition analysis to select a group of patients with a similar, novel MRI-pattern and subsequently performed whole-exome-sequencing to identify the mutated gene. Patients' fibroblasts were examined for biochemical consequences of the mutant protein. Six patients from five unrelated families were identified with a similar MRI-pattern showing predominant abnormalities of the cerebellar cortex, deep cerebral white matter and corpus callosum. The four tested patients had a complex I deficiency. Exome-sequencing performed in two patients revealed mutations in *NUBPL*, encoding an iron-sulfur cluster assembly factor for complex I. In one of the two patients only one heterozygous missense mutation was detected. Sanger sequencing revealed the second mutation, and *NUBPL* mutations in all other patients. Upon identification of the mutated gene, the MRI of the previously published case with *NUBPL* mutations was analyzed, which showed exactly the same pattern. A decreased amount of NUBPL protein and fully assembled complex I was found in patients' fibroblasts. Analysis of the effect of mutated NUBPL on the assembly of the peripheral arm of complex I indicated that NUBPL is involved in assembly of iron-sulfur clusters early in the complex I assembly pathway. Our data show that *NUBPL* mutations are associated with a unique, consistent MRI-pattern, which facilitates fast diagnosis and obviates the need for other tests. Whole-exome sequencing can provide a quick diagnosis, however, caution is warranted because certain mutations can be missed.

Pioglitazone prevents mitochondria dysfunction and halts axonal degeneration in a mouse model of X-adrenoleukodystrophy

A. Pujol[1], *L. Morato*[1], *J. Galino*[1], *M. Ruiz*[1], *M. Portero-Otin*[2], *R. Pamplona*[3], *I. Ferrer*[4];

[1]*IDIBELL, Barcelona, Spain,* [2]*University of Lleida, Barcelona, Spain,* [3]*University of Lleida, Lleida, Spain,* [4]*Institute of Neuropathology of Bellvitge, Barcelona, Spain.*

Accumulating evidence shows that oxidative stress and mitochondria dysfunction play a major role in the pathogenesis of axonal degeneration in multifactorial conditions such as Alzheimer's disease, Parkinson disease or amyotrophic lateral sclerosis. We have addressed the interplay of both noxious factors in adrenoleukodystrophy (X-ALD, OMIM: 300100), a peroxisomal disorder caused by loss of function of the ABCD1 transporter, leading to accumulation of very long-chain fatty acids (VLCFA) in organs and plasma. The mouse model for X-ALD exhibits a late-onset neurological phenotype with locomotor disability and axonopathy in spinal cords resembling the most common phenotype of adrenomyeloneuropathy patients. Recently, we identified oxidative damage and energetic failure as an early event in life, and the excess of VLCFA as a generator of radical oxygen species (ROS) and oxidative damage in X-ALD. Here, we uncover a mitochondrial impairment and depletion due to an impairment of mitochondria biogenesis via the PPARγ/PGC-1α pathway, which is also observed in brain white matter of X-ALD patients. We thus investigated the therapeutic effect of pioglitazone, an antidiabetic drug and a PPARγ agonist, in a preclinical test. Oral administration of pioglitazone restored mitochondria DNA and protein contents and expression of master regulators of biogenesis, neutralized oxidative damage to proteins and DNA, and reversed bioenergetic failure in terms of ATP levels, NAD^+/NADH ratios, and pyruvate kinase activities. Most importantly, the treatment halted locomotor disability and axonal damage in X-ALD mice. These results constitute a strong rationale for a phase II multicentric clinical trial for adrenomyeloneuropathy patients.

Cortical malformations, such as lissencephaly and subcortical band heterotopia (SBH), are associated with intellectual disability and pharmacoresistant epilepsy. Mouse mutant models for three genes mutated in SBH, *Doublecortin* (*DCX*), *LIS*1 and *alpha1-tubulin* (*TUBA1A*), do not show abnormally positioned heterotopic neurons in the neocortical white matter. On the other hand, the spontaneously arisen *HeCo* mouse mutant displays this phenotype. By whole genome genotyping and gene expression studies, we identified *Eml*1 as the mutated gene in *HeCo* mice. A retrotransposon insertion disrupts the gene, creating aberrant transcripts. Compound heterozygous mutations were identified in human *EML*1 in one family showing an atypical form of giant heterotopia. *Eml*1 codes for a microtubule-associated protein, not previously studied in cortical development. We show its expression in proliferation zones and the cortical plate, and *HeCo* mice have ectopic proliferation, which seems to be the primary cause of heterotopia in this model. Eml1 shows a punctate labeling, partially associated with microtubules in both progenitors and post-mitotic neurons. A patient missense mutation affects the microtubule association. In neuronal progenitors, Eml1 shows a cell cycle- dependent localization, enriched in the midbody region during late mitosis. We thus identify a new corticogenesis gene, and study of Eml1 and the *HeCo* phenotype reveal novel insights into heterotopia formation. Eml1 plays a role in neuronal progenitors and our data makes a link between ectopic progenitors in the developing cortical wall and severe heterotopia in human.

Intellectual disability (ID) is a genetically highly heterogeneous disorder that is frequently caused by *de novo* mutations. Recently, we showed that in about 30-50% of patients *de novo* mutations in known or candidate ID genes can be identified.[1,2,3] For candidate ID genes, it is often difficult to ascertain whether the *de novo* mutation is causative for the patients phenotype. To objectively determine the association of a novel candidate gene with the patients phenotype, the most important criterion is the identification of recurrent mutations in patients with an overlapping phenotype. Therefore, we tested an additional cohort of 765 patients with unexplained ID for mutations in 8 of these novel candidate ID genes, including *DEAF1*. We identified *de novo* mutations in *DEAF1* in three patients. All three patients showed severe ID with a disproportionally severely affected speech. We used functional assays to determine the impact of the mutations on the protein function. In addition, we performed functional studies of *DEAF1* in the fruit fly and zebrafish to further implicate this gene in the phenotype of the patient. In conclusion, we show that transcription factor *DEAF1* is a recurrently mutated gene in three patients with non-syndromic ID with severe speech impairment and we provide supportive functional evidence that links *DEAF1* to the patients phenotype.

Tel2-interacting proteins 1 and 2 (TTI1 and TTI2) physically interact with TEL2 (telomere maintenance 2) to form a conserved trimeric complex called the Triple T complex. This complex is a master regulator of phosphoinositide-3-kinase-related protein kinase (PIKKs) abundance and DNA damage response signaling. Using a combination of autozygosity mapping and high-throughput sequencing in a large Algerian consanguineous multiplex family, we found that a missense p.I436N mutation in *TTI2* causes a human autosomal recessive condition characterized by severe cognitive impairment, microcephaly, behavioral troubles, short stature, skeletal anomalies and facial dysmorphic features in three affected sibs. Immunoblotting experiment showed a drastically impaired stability of each subunit of the Triple T complex in patient skin fibroblasts. Consistently, a significantly reduced steady-state level of the two PIKKs tested, ATM and DNA-PKcs were observed in patient cells. Likewise, testing the serum dependant p70-S6Kinase phosphorylation we also found a defective mTOR signaling in patient cells. Combined with previous observations, these findings assess the role of the TTI2 gene in the aetiology of intellectual disability and further support the hypothesis of a crucial role of PIKK signaling in brain development and functioning.

KIF genes encode different motor proteins that are supposed to have fundamental roles in brain functioning, development, survival and plasticity, by regulating transport of cargoes along microtubules within the axons, dendrites and synapses of neurons. Studies in mouse models support the important functions of KIF genes in the nervous system. Reports that relate KIF genes to human Intellectual disability (ID) phenotypes are rare.
We report the clinical characteristics of individuals with mutations in the kinesin superfamily (KIF) genes KIF4A and KIF5C identified by next generation sequencing approaches. Four males from an X-linked family with a mutation in KIF4A (c.1489-8_1490delins10; p.?- exon skipping) showed mild to moderate intellectual disability (ID) and epilepsy. Furthermore, we identified one familial form and one sporadic patient with de novo dominant missense mutations in KIF5C who presented with severe ID, epilepsy and microcephaly. Interestingly, cerebral MRIs in these cases revealed cortical malformation indicative for a role of KIF5C in neuronal migration. To find

further supportive evidence of the involvement of KIF4A and KIF5C in observed ID phenotypes, we studied the effects on synaptic function of knockdown of these genes in rat primary neurons. At the functional level we found that both, Kif4a and Kif5c altered the balance between excitatory and inhibitory synaptic efficacy leading to changed neuronal excitability. Therefore, we believe that distortion of the balance between excitatory and inhibitory excitability at the synapse by KIF4A and KIF5C is a major mechanism in pathophysiology of the phenotype observed in our cases.

C08.5

Abnormal expression of sex biased genes in PCDH19-female limited epilepsy and intellectual disability (PCDH19-FLE) suggests a role for neurosteroid hormones.

*C. Tan[1], C. Shard[1], K. Hynes[1], E. Douglas[2], L. S. Nguyen[1], M. Corbett[1], G. Buchanan[1], E. Ranieri[2], R. Guerrini[3], C. Marini[3], S. F. Berkovic[4], I. E. Scheffer[4], **J. Gecz**[1,2];*
[1]The University of Adelaide, North Adelaide, Australia, [2]SA Pathology, North Adelaide, Australia, [3]University of Florence, Florence, Italy, [4]The University of Melbourne, Melbourne, Australia.

PCDH19-Female-Limited-Epilepsy (PCDH19-FLE) is an unusual X-linked disorder that primarily affects females. PCDH19-FLE encompasses a broad clinical spectrum from early infantile epileptic encephalopathy resembling Dravet syndrome to epilepsy with or without intellectual disability and behavioural problems, including autism. PCDH19-FLE is highly but not fully penetrant. We have tackled the questions of molecular pathogenesis of PCDH19-FLE by examining the transcriptomes of primary skin fibroblasts of PCDH19-FLE females (n=12 and n=3 age and passage matched normal controls) and unaffected transmitting males (n=3 and n=3 age and passage matched control males). We found that the expression of genes, which normally show sex (male/female) biased expression in this cell type, was significantly altered (observed = 43/94 vs expected = 223/19223, p=1.09 x 10-55, two-tail Fisher's exact test). Followup studies (including additional skin fibroblast cell lines) validated at least ~60% of selected genes. From among several plausible biological candidates we focused our attention on the aldo-keto reductase family 1, member C1-3 (AKR1C1-3) genes, which play crucial role in neurosteroid hormone metabolism (which skin is endowed with). Additional support for steroid and neurosteroid hormone role in the pathology of PCDH19-FLE came from the age of onset (mean ~10 months) and offset (mean ~12.5 years) of epilepsy (n=100 patients), both of which coincide with dramatically varying sex hormone levels (onset - after 'minipuberty' and offset - with the advent of puberty). This led us to postulate the neurosteroid hypothesis, which may explain PCDH19-FLE and opens realistic opportunities for targeted therapeutic interventions.

C08.6

Identification of Single-minded 2 (Sim2) binding sites by ChIP-Seq; understanding of the regulatory network of chromosome 21 transcription factors

***A. Letourneau**[1], G. Cobellis[2], E. Falconnet[1], A. Vannier[1], F. Santoni[1], M. Guipponi[1], C. Borel[1], S. E. Antonarakis[1,3];*
[1]Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland, [2]Department of Biophysics, Biochemistry and General Pathology, Seconda Università di Napoli, Napoli, Italy, [3]iGE3 Institute of Genetics and Genomics of Geneva, Geneva, Switzerland.

Down syndrome (DS) results from trisomy of chromosome 21 (HSA21). Some DS phenotypes may be directly or indirectly related to the increased expression of specific HSA21 genes, in particular transcription factors. The HSA21 Single-minded 2 (SIM2) transcription factor has key neurological functions and appears therefore as a good candidate for some DS features, in particular mental retardation. In order to identify the DNA binding sites and downstream targets of SIM2, we performed three independent chromatin immunoprecipitations and high-throughput sequencing (ChIP-Seq) on a mouse embryonic stem cell (mESC) line that stably overexpresses a Flag-tagged mouse Sim2 under the control of a Tet-off system. ChIP and input DNAs were sequenced on the Illumina HiSeq 2000. Reads uniquely mapped with BWA were submitted to HOMER for the identification of Sim2 targets and the discovery of binding site motifs. We obtained a list of 2373 putative binding sites for Sim2. Importantly, as opposed to other regions, the promoters were significantly over-represented in the list of Sim2 binding sites (p-value 9.3E-12). A gene ontology analysis on the nearby genes revealed enrichment for biological processes potentially related to Sim2 functions such as transmission of nerve impulse or ectoderm development. The RNA-Seq transcriptome of the Sim2 expressing and non-expressing mESC is currently under investigation in order to correlate the Sim2 binding sites with putative target genes. All together, those results suggest the role of a Sim2-related gene network in DS neuronal features and emphasize the importance of the functional characterization of HSA21 transcription factors.

It has been hypothesized that low-frequency genetic variants in coding regions of genes, in aggregate, explain a substantial fraction of the heritability of common diseases. We sequenced the exomes of 1,000 Danish cases with type 2 diabetes, BMI > 27.5 kg/m^2, and hypertension and 1,000 controls to an average depth of 56x. Simulations suggest our study has substantial statistical power to detect at least one causal gene if the heritability of these common diseases is explained by rare variants in the coding regions of a limited number of genes. We applied a series of gene-based tests to detect such susceptibility genes. However, no gene showed a significant association to disease risk after correcting for the number of genes analyzed. Thus, we can reject a model for the genetic architecture of type 2 diabetes, obesity and hypertension, where much of the missing heritability is explained by rare non-synonymous variants clustered in a small number of genes.

C09.2

Haplotype sharing reveals fine-scale demographic history

***P. Palamara**[1], T. Lencz[2], A. Darvasi[3], I. Pe'er[1], The Genome of the Netherlands Consortium;*
[1]Columbia University, New York City, NY, United States, [2]The Zucker Hillside Hospital Division of the North Shore-Long Island Jewish Health System, New York City, NY, United States, [3]Hebrew University of Jerusalem, Jerusalem, Israel.

Identical-by-descent (IBD) chromosomal segments shared by pairs of individuals can now be reliably detected in large genomic datasets of purportedly unrelated samples, and summary statistics of IBD sharing were recently shown to convey information about population-level features such as demography, natural selection and heritability of common traits. We present analytical results for the relationship between haplotype sharing and demography, and show how IBD sharing can be used to infer the demographic history of the recent millennia, where classical methods are typically underpowered. We analyzed 500 Ashkenazi Jewish samples, finding evidence for two periods of expansion, separated by a strong bottleneck. In the reconstructed model, an effective population of tens of thousands of individuals is first drastically reduced to ~300 founders in the 12th century A.D, then ra-

pidly expands (exponential rate ≈ .28) to a modern population of millions of individuals. Analyzing IBD sharing in 56 Kenyan Masai, high levels of cryptic relatedness are pervasive. While this may suggest a strong recent bottleneck (exponential rate ≈ -.14), we show that a model of multiple small-sized demes interacting through high migration rates, consistent with the social structure of this population, results in a compatible pattern of haplotype sharing. We finally analyzed 498 individuals from several Dutch provinces (the Genome of Netherlands dataset) finding evidence for population growth and substantial migration across these groups in the recent millennia.

C09.3

Signatures of selection in the Genome of the Netherlands Project

C. C. Elbers*, *S. L. Pulit**, L. C. Francioli, A. Menelaou, P. I. W. de Bakker, Genome of the Netherlands Consortium, * these authors contributed equally;*
Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands.

The Genome of the Netherlands Project (GoNL) sequenced 250 pedigrees of Dutch ancestry at 12x coverage in collaboration with BGI (Shenzhen, China).
Using all unrelated samples (N=498), we sought to identify regions in the Dutch genome that show unusual allele frequency spectra, which could indicate evidence of selection. Therefore, we calculated Tajima's D values in 100-kb windows across the genome, stratifying variants by function.
Our results show that the mean Tajima's D value is lower for exonic regions, compared to non-exonic regions ($p=3.6x10^{-19}$). This observation reflects allele frequency distributions that are shifted toward rare variants in these exonic regions, a pattern that can be explained by purifying selection. Furthermore, we studied the regions showing the 5% lowest and highest Tajima's D values by looking for significant overrepresentation of sequence features, pathways and diseases genes. 1603 genes map to the 5% of regions with the lowest Tajima's D. This group of genes is enriched for genes with alternative splicing products ($p=4.1x10^{-13}$) and height genes ($p=5.6x10^{-6}$). 853 genes map to the 5% regions with the highest Tajima's D and here we found an overrepresentation of genes involved in olfactory transduction ($p=3.3x10^{-25}$) and various immune traits (P<0.001). Unsurprisingly, the MHC region mainly drove results in immune traits.
Overall, we conclude that our analysis demonstrates evidence for purifying selection in exonic regions of the Dutch genome. Furthermore, our results suggest signatures of selection for regions containing height, smell and immunity genes. We are currently pursuing alternative methods for detecting genomic regions under evolutionary selection.

The T2D-GENES consortium aims to identify cosmopolitan and population-specific variants associated with type 2 diabetes (T2D) and related traits. To do this, we undertook whole-exome sequencing of >10,000 individuals from five ethnic backgrounds, including African-Americans, Mexican-Americans, Europeans (Finnish and Ashkenazim), South Asians (Indian Asians from London and Singapore), and East Asians (Chinese in Singapore and Koreans), half of whom were diagnosed with T2D. We present here initial results from 5,334 individuals (African-American, East and South Asian) for lipids. We tested the hypothesis that low frequency (LF, MAF<5%) variants contribute to variation in lipid levels. We identified 1.8 million exome variants, 91% rare (MAF<0.5%), 5% LF, and 4% common. In covariate-adjusted, single-variant fixed-effects meta-analyses, we have detected genome-wide significant associations ($p<5x10^{-8}$) within known GWAS signals: *CETP* ($p=1.03x10^{-10}$) and *LIPC* ($p=1.9x10^{-8}$) for HDL, *TOMM40* ($p=6.6x10^{-14}$) and *PVRL2* ($p=1.7x10^{-8}$) for LDL, and *APOA5* ($p=7.8x10^{-19}$) for triglycerides. There were suggestive associations at *APOA5* ($p=9.9x10^{-8}$) and *LPL* ($p=4.9x10^{-7}$) for HDL, and *ADAMTSL3* ($p=1.6x10^{-6}$) for LDL. LF variant analysis employing aggregate tests with SKAT across all individuals identified associations with the several previously-implicated genes including *CETP* ($p=1.4x10^{-7}$) and *APOA5* ($p=2.7\ x10^{-6}$) for HDL, and *PCSK9* ($p=3.6x10^{-6}$) for LDL. Novel signals were seen at *ACPP* ($p=3.1x10^{-6}$) for HDL, *ZNF626* ($p=1.47x10^{-4}$) for cholesterol, *MYBPC1* ($p=3.7x10^{-5}$) for LDL, and *c2orf19* ($p=5.9x10^{-5}$) and *TMEM171* ($p=6.5x10^{-5}$) for triglycerides. Whole exome sequencing of a multiethnic sample allows evaluation of effects across the full allele frequency spectrum in coding regions and identification of novel variants contribution to lipid trait variability.

C09.5

Exome sequence analysis of type 2 diabetes in over 10,000 samples from five ancestry groups: the T2D-GENES Consortium.

M. A. Rivas[1], *T. M. Teslovich*[2], *A. Morris*[1], *P. Fontanillas*[3], *A. Mahajan*[1], *X. Sim*[4], *J. Flannick*[3], *N. P. Burtt*[3];
[1]*University of Oxford, Oxford, United Kingdom,* [2]*Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, United States,* [3]*Broad Institute, Cambridge, MA, United States,* [4]*Department of Biostatistics and Center for Statistical Genetics, University of Michigan,, Ann Arbor, MI, United States.*

We have undertaken whole-exome sequencing of >10,000 type 2 diabetes (T2D) cases and controls from five major ancestry groups: African American (AA), East Asian (EA), European (EU), Hispanic American, and South Asian (SA). The unique study design will yield a catalogue of coding variation across diverse populations, enabling us to: 1) identify novel T2D association signals; 2) assess evidence for heterogeneity in genetic effects between ancestries; and 3) localize causal variants for T2D.
Sequencing of the first 5,334 individuals (50% cases) of AA (N=1069), EA (N=2163), EU (N=962), and SA (N=1140) ancestry has identified ~1.8M single nucleotide variants (SNVs). Only 81k (5%) are present in all four ancestry groups, 81% of which have minor allele frequency (MAF) >5%. Conversely, the 28%, 31%, 4% and 21% of variants unique to AA, EA, EU and SA ancestries are largely rare (MAF <1%).
Using fixed-effects meta-analysis of single variant association results we identified rs2233580 (p.R192H) to be associated with T2D at genome-wide significance. The association was specific to the EA samples: Korean (p=1.4x10-4, 8% MAF) and Singapore Chinese (p=7.4x10-6, 13% MAF). The variant was monomorphic in AA and EU samples. It was recently shown that p.R192H impairs PAX4's ability to repress transcription of insulin and glucagon. In 5,334 samples, no low-frequency or rare causal variants have been identified using single marker or gene-level tests.
We anticipate that analysis of all 10,000 exomes (early 2013) may identify additional association signals for T2D and provide functional insights into the pathogenesis and genetic architecture of T2D.

C09.6

Lessons learned from the NHLBI-Exome Sequencing Project (ESP)

S. M. Leal*, on behalf of NHLB-ESP;*
Baylor College of Medicine, Houston, TX, United States.

The NHLBI-Exome Sequencing Project (ESP) was conceived to identify rare, putatively functional coding variants associated with heart, lung, and blood related complex traits. To this end, exome sequence data was generated on 4,420 European Americans and 2,312 African Americans who are participants in several large cohort studies. Sequenced individuals included a deeply phenotyped random sample, quantitative trait extremes of interesting phenotypes (e.g., low-density lipoprotein and blood pressure) and disease cases (e.g., early onset myocardial infarction or stroke). Over 80 heart, lung, and blood phenotypes were available for analysis. Given that this is one of the largest medical sequencing studies ever undertaken, it was necessary to develop efficient methods and pipelines for variant cal-

ling, data quality control, analysis, and interpretation of millions of single nucleotide variants from thousands of samples across multiple phenotypes. These methods allowed us to identify novel associations. For instance, we discovered and validated an association between variants in the DCTN4 gene and risk of pseudomonas infection in individuals with cystic fibrosis (n=91, p<2.5x10-6). We also replicated several known associations across a number of traits [e.g., variants in the APOB gene are associated with LDL (p<2.5 x 10-6, n=3342) and the LEPR gene is associated with C-reactive protein (p<2.5x10-6, n=1791)]. The ability to detect associations was very dependent on the genetic architecture. NHLBI-ESP not only provides novel information on the genetic etiology of several heart, lung, and blood related traits, but also offers guidance on using exome sequencing to identify rare variants associated with complex traits.

S.M. Leal: None.

C10.1

From personal genetic counseling to public health screening: The BRCA Opportunity

S. Lieberman[1], *A. Tomer*[1], *A. Ben-Chetrit*[2], *O. Olsha*[3], *T. Zalut*[4], *A. Lahad*[5], *E. Levy-Lahad*[1]; [1]*Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel,* [2]*IVf unit, Shaare Zedek Medical Center, Jerusalem, Israel,* [3]*Surgery Department, Shaare Zedek Medical Center, Jerusalem, Israel,* [4]*Emergency Unit, Shaare Zedek Medical Center, Jerusalem, Israel,* [5]*Public Health Department, the Hebrew University of Jerusalem, Jerusalem, Israel.*

BRCA1/2 carriers have increased breast/ovarian cancer risks and are identified based on personal/familial history, through Cancer Genetics clinics providing both pre- and post-test counseling. Among Ashkenazi Jews (AJ) there is a high frequency (2.5%) of three *BRCA1/2* mutations, and ~40% of carriers have no significant family history. These exceptional characteristics suggest that in AJ, BRCA screening fulfills WHO screening criteria. However, the traditional counseling process is difficult to implement on a large scale. We aimed to examine the feasibility of BRCA screening in Israel, using an alternate counseling model.

Screening was offered to healthy AJ, age ≥30, in various medical settings, without pre-test counseling. Risk assessment was based on a self-reported family history questionnaire. Only carriers and high risk participants received post-test counseling. Feelings, knowledge and attitudes toward testing were examined using questionnaires at 2 weeks and 6 months.

1,561/2600 (60%) individuals agreed to be screened, and 28 carriers (1.8%) were identified. Over 90% were satisfied with participation. Mean knowledge score was 70%. Post-test stress was reported by 1.5% at time 2 weeks but resolved in all by 6 months. Only 1% opposed BRCA population screening. Screening led to counseling in 423 (27%) high risk participants who had not been previously referred. 39% of carriers had non-suggestive family history and would not have been identified without screening.

Lack of pre-test counseling is unorthodox, but our results suggest high levels of satisfaction and coping with this process. These results will inform future implementation of genetic advances into the public health arena.

Background: Due to the epidemiological transition, the emerging economies of China, East Asia, India, Latin America, the Middle East and South Africa are facing an increasing proportion of morbidity and mortality due to congenital and genetic conditions, a rising need for genetic services to improve patient outcomes and overall population health and the challenge how: (i) to ensure the successful translation of genetic/genomics laboratory and academic research into quality assured pathways, (ii) to develop a service delivery infrastructure that leads to equitable and affordable access to high quality genetic/genomic testing services.

Objectives: To document and compare current practices and the state of genetic service provision in: Argentina, Brazil, China, Egypt, India, Oman, Philippines and South Africa and to identify current knowledge gaps and unmet service needs.

Methods: A standardized survey that is the first of its kind worldwide that allows comparison of services across a number of key dimensions by using a core set of indicators selected by the GenTEE consortium for their relevance.

Results: Underfunded fragmented public services, increasing out-of-pocket expenses for genetic testing services, concentration of services in main cities and skill gaps result in inequitable services or delayed access. The development of services in the private sector is opportunistic and mostly technology and market driven. There is a marked lack of standard operating procedures and agreed quality assessment processes for new technologies.

Discussion: International collaborative networks can provide support for capacity building and help to strengthen the provision of quality genetic/genomic services in emerging economies.

C10.3

Incidental findings in research: National Health Service Research Ethics Committee member perspectives.

L. M. Jackson, *L. Goldsmith, A. O'Connor, H. Skirton;*
Plymouth University, Plymouth, United Kingdom.

Genetic healthcare is in the midst of a transition towards genome-wide technologies, driven by the increasing availability of affordable sequencing. The possibility of discovering genetic and genomic incidental findings, outside the scope of the initial objective but with potential health implications, is significant when utilising such an approach.

Issues concerning the obligations to search for and report these findings are extensively discussed in opinion articles, commentaries and ethical discussions. However there is a paucity of primary research data available for analysis as evidenced by a recent systematic review of empirical research that included only four relevant studies.

Following on from our work with members of the public and genetic counsellors, in this phase of the study we sought the opinions of United Kingdom National Health Service Research Ethics Committee members (n=30) who are responsible for approving protocols for research studies. Semi-structured telephone interviews were conducted and transcripts were analysed using thematic analysis to identify common themes.

Participants discussed the requirement for extensive information and appropriate consent forms to facilitate informed decision making, support for return of clinically actionable findings and the need for the researcher to take responsibility for disclosure decisions, although there was no consensus on any one issue. Participants were divided on whether patient autonomy or patient wellbeing should take precedence.

This study provided a useful insight into the opinions of the ethics committee members. However it is clear that guidelines on the issue are essential to ensure equitable research ethics decisions across the UK.

C10.4

Preferences for priority setting criteria in genetic testing: a discrete choice experiment

F. Severin[1], *W. Hess*[2], *J. Schmidtke*[3], *A. Mühlbacher*[4], *P. Meyer*[5], *W. Rogowski*[1,6];
[1]*Helmholtz Zentrum München, German Research Center for Environmental Health, Institute of Health Economics and Health Care Management (IGM), Neuherberg, Germany,* [2]*Lund University, Sweden, Department of Economics and Centre for Economic Demography, Lund, Sweden,* [3]*Hannover Medical School, Institute for Human Genetics, Hanover, Germany,* [4]*Hochschule Neubrandenburg, IGM - Institut Gesundheitsökonomie und Medizinmanagement, Neubrandenburg, Germany,* [5]*University Medicine Rostock, Institute of Medical Genetics, Rostock, Germany,* [6]*Ludwig-Maximilians-University, Institute and Outpatient Clinic for Occupational, Social and Environmental Medicine,*

Clinical Center, Munich, Germany.

Given the need of many European health care systems to contain costs of public health care, decisions about prioritizing genetic tests may have to be made. Different criteria have been proposed to guide the process of priority setting, but little is known about the relative weights that should be assigned to them in decision making. This study assesses stakeholder preferences for weighting these criteria in order to support priority setting decision making throughout Europe. In a discrete choice experiment respondents made binary choices between testing options that were described by medical and non-medical criteria. Attributes considered included severity of the disease, risk for the disease, aim of the test, medical benefit of the test, and costs of the test. Responses from 594 participants (including 171 clinical geneticists, 151 laboratory scientists, 83 academic researchers, and 98 patient representatives) were analysed. The most valued attribute levels were a proven medical benefit of the test, high risk for having the disease, and low costs of the test. Some preferences differed between clinicians, patients, and other genetic experts. While clinicians attached greater value on attribute levels referring to risk for having the disease and proven medical benefit of the tests, patients and other stakeholders had increased preferences for testing highly severe conditions. Priority weights determined by scientific methods may help to improve the consistency of priority setting in genetics. Limitations include that the weights might vary by context, and that evidence for operationalizing the criteria is limited for most genetic tests.

Context
Identification of patients at risk for hereditary cancers is essential to inform decisions about early screening, genetic testing, and pre-symptomatic risk reducing options. However, if non-genetic specialists (e.g. general practitioners (GPs)) are to make an effective contribution in this area, competencies need to be upgraded.
Objective
To investigate whether multifaceted oncogenetics training for GPs sustainably improves knowledge and consultation skills, and to evaluate participants' satisfaction with the training and perceived applicability learned.
Interventions
1) Genetics e-learning Continuing Professional Development (G-eCPD) module aimed at improving GPs' oncogenetics knowledge
2) Four-hour interactive live training module covering oncogenetic clinical skills (family history, risk assessment, and efficient referral).
Evaluation Methods
Two parallel-group pre-post-retention (6-month follow-up for G-eCPD, 3-month follow-up for live module) controlled group intervention trials (standardized patients, checklists and validated questionnaires) were conducted. 168 GPs working in the Dutch primary care setting responded to an email invitation and were randomly assigned to intervention or control groups, evaluating the G-eCPD module (n=80, 44 GPs completed all measurements) or the live module (n=88, 56 GPs completed all measurements).
Results
There was a significant follow-up improvement in oncogenetic knowledge (G-eCPD) and consultation skills (live module) after the intervention. Satisfaction and self-perceived applicability was high.
Conclusions
The training proved to be a feasible and satisfactory method to achieve sustained
improvement of oncogenetic knowledge and consultation skills. This educational framework can inform future training activities for GPs and potentially other medical professionals to enhance genetics-related consultation and decision making with the ultimate aim of improving medical care.

The aim of this qualitative study was to describe the psychological impact of the diagnosis announcement of pathogenic Copy Number Variations (pCNVs). We performed semi-structured interviews of 60 parents of 41 affected children and 5 clinical geneticists who announced the diagnoses.
Medical doctors emphasized their difficulties in announcing diagnoses made by Chromosomal Microarray (CMA). The diagnosis of the best characterized microdeletion syndromes, defined by patronymic names, is generally clinically suspected and confirmed by Fluorescence In Situ Hybridization analysis. The pCNVs diagnosed by CMA, often named after cytogenetic formulas, are overall rarer and their phenotype and prognosis are less characterized: this can make doctors feel less confident in the diagnosis announcement.
In the presence of a patronymic name, 83% of parents were able to define their child's disease. The announcement of pCNVs named after cytogenetic formulas, on the contrary, did not appear to facilitate a mental representation of the disease, and the majority of parents found it difficult to provide a clear description of the disease. For 13% of them, the genetic diagnosis had "no meaning"; in some cases, the genotype-phenotype correlation was called into question.
The announcement of inherited pCNVs can increase the feeling of parental guilt. The disclosure of *de novo* pCNVs can induce a feeling of "breakage" in the mental representation of the parent-child vertical transmission.
In conclusion, our study shows that the disclosure of pCNVs has a significant psychological impact: a multidisciplinary approach to the diagnosis announcement, including psychological support, should be systematically warranted.

Kloosterman*[1];

[1]*UMC Utrecht, Utrecht, Netherlands,* [2]*Life Technologies, Beverly, MA, United States.*

Ovarian cancer (OC) is a leading cause of death from gynaecological malignancies, with approximately 225,000 new cases and 140,000 deaths reported worldwide yearly. OC has a unique intra-abdominal metastatic spread and is associated with high morbidity, over 70% of patients present with advanced disease at diagnosis. Advances in genome sequencing have expanded our understanding of the complexity of carcinogenesis and have given insight into inter- and intra-individual heterogeneity of cancer genomes. Here, we present the first systematic and comprehensive study on 3D topography of structural variations, point mutations and RNA expression within tumours. We obtained tissue from 8-20 primary and metastatic sites per patient from three treatment-naïve stage III/IV OC patients. Structural- and copy number variations and their effect on gene expression are detected with high sensitivity by a combination of next-generation sequencing techniques. Bioinformatic cross-sample analysis reveals extensive heterogeneity on multiple levels between primary and metastatic lesions within one patient. Phylogenetic analysis further revealed two very distinct evolutionary

paths: a more linear evolution in one patient and a parallel evolution pattern in the other two. In the latter, a branching event occurring very early in tumour development has led to highly diverge metastatic clones differing both in structural variation and point mutation content. This finding was surprising, as these genetic differences were not expected based upon the histological profiles. Our study provides a foundation of experimental methods able to generate evolutionary models for cancer, leading to the identification of genetic drivers for tumour formation and metastatic spread.

Germinal-center B-cell derived lymphomas (GCB-lymphomas) are the most common B-cell lymphomas. They include follicular (FL), diffuse large B-cell (DLBCL) and Burkitt lymphomas (BL), as well as intermediate DLBCL/BL (IL). In the framework of International Cancer Genome Consortium (ICGC) the ICGC MMML-Seq-Project funded by the German Federal Ministry of Education and Research (01KU1002A-J) explores whole genome sequencing data of currently 29 GCB-lymphomas and paired normal controls. Genomic sequencing is complemented by transcriptome, miRNAome and whole methylome sequencing. In the 23 yet finished whole genomes (>30x) we identified a median of 35 potentially protein-changing mutations in BL, 58 in DLBCL/IL, and 40 in FL. Recurrently mutated genes include TP53, MYC, SMARCA4, CCND3, MLL2 and ID3, the latter being a novel hallmark of BL (Richter et al., Nat Genet 2012). On the genome-wide level, we identified a median of 4221 small variants in BL, 10782 in DLBCL/IL, and 6705 in FL. Regional clustering of single nucleotide variants (SNVs) was observed which particularly affected regions undergoing somatic hypermutation in B-cells. Investigation of SNV mutation types in the context of the neighboring bases provided evidence for different mutational mechanisms. Structural variants point to novel fusion genes which in part were supported by fusion transcripts. Patterns of SNVs, structural variants and transcriptional profiles differed between BL and the other GCB-lymphomas. Our ongoing complete genomic and transcriptomic sequencing efforts within the ICGC, thus, provide insights into the different mutational mechanisms and driving genes active in the various subtypes of GCB-lymphomas.

FAS/FASL pathways is impaired in chordoma and is involved in notochord development and regression

***L. Ferrari[1]**, A. Pistocchi[1,2], A. Calastretti[1], L. Libera[1], N. Boari[3], G. Canti[1], P. Mortini[3], F. Cotelli[2], P. Riva[1];*

Chordoma, a malignant bone tumor arising from notochord remnants, is characterized by unforeseeable prognosis and chemoresistance. Since the apoptotic pathway mediated by FAS-FASL was found to be involved in notochord regression, we studied their expression in 31 chordomas and in the U-CH1 cell line. The lack of FASL expression in most of the chordomas and the detection of FAS anti-apoptotic, besides the pro-apoptotic isoform, in both tumors and U-CH1 cells, are consistent with Fas/Fasl pathway inactivation, also supported by the prevalent detection of the Caspase 3 and Caspase 8 inactive forms. Moreover, we observed that apoptosis was induced in U-CH1 cells following treatments with soluble Fasl, besides the increasing of active Caspase 8. To elucidate the role of FAS/FASL pathway in chordoma development, we started in vivo studies on zebrafish. fas and fasl homologue genes were found to be maternally expressed during development and fas in all zygotic stages, while fasl from 48 hours post fertilization. We then detected fasl expression in notochord, muscles and central nervous system at 5 days post fertilization by immunohistochemistry. Following fas and fasl knock down by morpholino oligos, we observed notochord anomalies such as packed notochordal cells, curved bodies and bent tail. Moreover, the notochord morphology was characterized by bigger notochordal cells compared to the control and the perinotochordal sheath showed an anomalous wavy strand. The obtained results strongly suggest the implication of FAS/FASL in chordoma tumorigenesis, providing new insights on notochord development/regression and helping to address the identification of chordoma pharmacological targets.

C11.4

SDHB mutations link pheochromocytoma/paraganglioma mailgnancy to epithelial to mesenchymal transition, both in human tumors and in SDHB-/- chromaffin cells

***C. Loriot[1,2]**, M. Domingues[3,2], A. Berger[4,5], N. Burnichon[1,2,6], C. Martinelli[1,2], L. Vescovo[7], E. Letouzé[7], J. Sael[4,5], L. Larue[3,2], A. Gimenez-Roqueplo[1,2,6], J. Favier[1,2];*
[1]Inserm U970, Paris Cardiovascular research center, Paris, France, [2]Université Paris Descartes, Sorbonne Paris Cité, Faculté de médecine, Paris, France, [3]CNRS UMR3347, INSERM U1021, Institut Curie, Orsay, France, [4]Inserm S968, Institut de la vision, Paris, France, [5]Université Pierre et Marie Curie, Paris, France, [6]AP-HP, Hôpital Européen Georges Pompidou, Service de Génétique, Paris, France, [7]Programme Carte d'identité des tumeurs, Ligue nationale contre le cancer, Paris, France.

Pheochromocytomas (PCC) and paragangliomas (PGL) are neuroendocrine tumors derived from chromaffin cells, genetically determined in 35% of cases. It is well established that SDHB gene mutations are associated with increased invasiveness and poor prognosis. The link between mutations in this subunit of a mitochondrial enzyme (succinate dehydrogenase) and PCC/PGL malignancy is still missing. The aim of our study was to address the role of epithelial to mesenchymal transition (EMT) in SDHB-mediated oncogenesis.
The unsupervised classification of transcriptome data of 188 PCC/PGL, based on 94 EMT-associated genes revealed that SDHB-malignant samples displayed the same pattern of gene expression, reflecting EMT activation: up regulation of LOXL2, TWIST1, TCF3, MMP1 and MMP2; down regulation of CDH2 (N-cadherin) and KRT19. At protein level, we demonstrated that all SDHB-malignant samples presented a nuclear translocation of SNAIL (a key EMT inducer transcription factor).
Using a Cre-Lox strategy, we generated an immortalized mouse chromaffin cell (imCC) line harboring an Sdhb gene knock-out that recapitulates most hallmarks of SDH-related PCC/PGL. Immunofluorescence and/or RTqPCR found the same type of variations in Sdhb-/- cells than in SDHB-mutated tumors. We studied cell migration by single cell tracking, wound scratch and

invasion assays, which revealed that Sdhb-/- cells had higher individual cell speed, global migration and invasiveness abilities. The functional validation of two EMT associated genes (KRT19 and SNAIL) with these processes is currently being investigated. We will further investigate the tumoral potential of Sdhb-/- cellular models using a renal capsule xenograft strategy, in order to develop preclinical studies testing innovative therapies.

Mismatch repair (MMR)-deficient human tumours develop through a particular molecular pathway characterized by the genetic instability of numerous microsatellite-type DNA repeats dispersed throughout the genome. To date, their pathogenesis is mainly attributed to truncating mutations occurring at coding repeats in cancer-related genes. Meanwhile, altered expression of microRNAs is being increasingly considered as a key event in carcinogenesis. This work sums up the studies we recently performed to investigate the possibility that 1. Deregulation of some microRNA targeting MMR proteins might constitute a pre-neoplastic event that promotes the emergence of MMR-deficient tumours and 2. Somatic mutations in MSI-targeted microRNA genes might help the MSI-driven tumourigenic process. MSI tumour initiation: miR-155 and miR-21 are two inflammation-related microRNAs that target core MMR proteins. Their overexpression was observed in the non-neoplastic mucosa (field-defect) of patients suffering from inflammatory bowel disease (IBD). Interestingly, the emergence of MSI in these rare clinical entities doesn't seem to be dependent on germline inactivation or promoter methylation of MMR proteins but is likely to be a microRNA-driven process (Svrcek *et al.*, 2013). MSI tumour progression: Our results provide evidence that DNA repeats contained in precursor or mature sequence of microRNAs are relatively rare and generally preserved from mutations, but can sometimes be highly mutated in MMR-deficient cancer cells (e.g. miR-1303, miR-567, miR-1273c) (El-Murr *et al.*, 2012). Based on both reports, we propose a model in which microRNA field-defects and MSI-targeted microRNA genes may act first, as initiators and second as drivers for MSI-driven transformation of the colonic mucosa.

C11.6

Western diet and *Mlh1* mutation predispose colonic mucosa to early inactivation of the Wnt signaling antagonist *Dickkopf-1*

M. Pussila[1], *L. Sarantaus*[1], *D. Dermadi Bebek*[1], *S. Valo*[1], *N. Reyhani*[2], *S. Ollila*[1], *E. Päivärinta*[1], *P. Peltomäki*[1], *M. Mutanen*[1], *M. Nyström*[1];
[1]*University of Helsinki, Helsinki, Finland,* [2]*Aalto University, Helsinki, Finland.*

Colorectal cancer (CRC) is the second most common cause of cancer-related deaths in the Western world and interactions between genetic and environmental factors, including diet, are suggested to play a critical role in its etiology. We conducted a long-term feeding experiment in the mouse to address epigenetic changes arising in normal colonic mucosa and their functional consequences as putative cancer-predisposing events available for early detection. The expression of 94 growth-regulatory genes previously linked to human colorectal cancer and aberrant hypermethylation was studied at two time points (5 weeks and 12 months of age) in the heterozygote *Mlh1*$^{+/-}$ mice analogous to human Lynch syndrome (LS), and wild type *Mlh1*$^{+/+}$ littermates, fed by either Western-style (WD) or AIN-93G control diet. In mice carrying *Mlh1* mutation and/or fed with WD, histologically normal proximal colonic mucosa, the predominant site of cancer formation in LS, exhibited a significant expression decrease in tumor suppressor genes, *Dkk1, Slc5a8, Hoxd1*, and *Socs1*. the reduced expression was associated with age-related promoter hypermethylation in these genes. As evidence of early epigenetic inactivation of *Dkk1* in particular, most mice showing high methylation no longer expressed *Dkk1* mRNA, while *Mlh1* showing only modest methylation was still expressed in both *Mlh1*$^{+/-}$ and *Mlh1*$^{+/+}$ mice. Furthermore, changes in *Dkk1* seem to predispose to neoplasia/hyperplasia in the proximal colon. This together with the methylation and expression data indicates that the inactivation of *Dkk1*, a secreted antagonist of the Wnt/β-catenin signaling pathway, is a remarkably prominent and early marker for colon oncogenesis.

Congenital poikiloderma associated with tendon contracture and pulmonary fibrosis was described in a South-African family with autosomal dominant inheritance by Khumalo *et al.* in 2006. Here, we report four sporadic cases affected with this syndrome in two males and two females (ages 6-30). Key features consist of: (i) congenital poikiloderma, hypotrichosis, hypohidrosis; (ii) progressive muscular weakness with feet varus deformation and (iii) pulmonary fibrosis. Muscle MRI shows diffuse fatty infiltration confirmed by muscle biopsy. Microscopy of the skin reveals elastic tissue degeneration with alterations of the elastic network.
Whole exome sequencing performed in the South African family and in the trio of one sporadic case led to the identification of a very strong candidate gene, unreported to date. The involvement of this gene has been confirmed by the detection of variations in the other cases. Taken together, three unrelated patients share exactly the same missense mutation; one other patient and the South-African family members carry two very close mutations. We suggest that these three mutations are involved in the same putative functional domain of the protein.
In conclusion, we report a phenotypically recognisable syndrome linked to a new gene. Functional studies are ongoing to better understand the pathophysiology of this entity.

Background
Childhood-onset pulmonary arterial hypertension (PAH) is rare and differs

from adult-onset disease in clinical presentation, with often unexplained developmental retardation and dysmorphic features (DR/DF). Mutations in the major PAH gene, *BMPR2,* was reported to cause PAH in only 10-16% of childhood-onset patients. We aimed to identify other genes associated with childhood-onset PAH.

Methods

We studied 20 children with PAH. Six patients with unexplained accompanying DR/DF were selected for array-comparative genomic hybridization analysis, with the aim of finding deletion regions containing candidate genes for PAH. Three patients had overlapping deletions of 17q23.2. *TBX2* and *TBX4* were selected from this area as candidate genes and sequenced in all 20 children. After identifying *TBX4* mutations in these children, we subsequently sequenced *TBX4* in a cohort of 49 adults with PAH. Because *TBX4* mutations are known to cause small patella syndrome (SPS), a lower limb malformation syndrome, all patients with newly detected *TBX4* mutations were screened for features of SPS. We also screened a third cohort of 23 patients with SPS for PAH.

Results

TBX4 mutations (n=3) or *TBX4*-containing deletions (n=3) were detected in 6 out of 20 children with PAH (30%). All living patients and two parents with *TBX4* mutations appeared to have previously unrecognized SPS. In the adult PAH-cohort, one *TBX4* mutation (2%) was detected. Screening in the cohort of (predominantly adult) SPS patients revealed no PAH.

Conclusions

These data indicate that *TBX4* mutations are associated with childhood-onset PAH, although the expressivity of PAH in adult *TBX4* mutation carriers is low.

Hypotrichosis simplex (HS) comprises a group of hereditary isolated alopecias that are characterized by a diffuse and progressive loss of hair starting in childhood and shows a wide phenotypic variability. We mapped an autosomal-dominant form of HS to chromosome 1q31.3-1q41 in a Spanish family. By direct sequencing, we identified the heterozygous mutation c.1A>G (p.Met1?) in SNRPE that results in loss of the start codon of the transcript. We identified the same mutation in a simplex HS case from the UK and an additional mutation (c.133G>A [p.Gly45Ser]) in a simplex HS case originating from Tunisia. SNRPE encodes a core protein of U snRNPs, the key factors of the pre-mRNA processing spliceosome. The missense mutation c.133G>A leads to a glycine to serine substitution and is predicted to disrupt the structure of SNRPE. Western blot analyses of HEK293T cells expressing SNRPE c.1A>G revealed an N-terminally truncated protein, and therefore the mutation might result in use of an alternative in-frame downstream start codon. Subcellular localization of mutant SNRPE by immunofluorescence analyses as well as incorporation of mutant SNRPE proteins into U snRNPs was found to be normal, suggesting that the function of U snRNPs in splicing, rather than their biogenesis, is affected. In this report we link a core component of the spliceosome to hair loss, thus adding another specific factor in the complexity of hair growth. Furthermore, our findings extend the range of human phenotypes that are linked to the splicing machinery.

C12.4

Gain-of-function mutations in the mechanically activated ion channel PIEZO2 cause distal arthrogryposis type 5

G. Houge[1], *B. Coste*[2], *R. L. Maas*[3], *A. Hoischen*[4], *S. R. Sunyaev*[3], *A. Patapoutian*[2];

[1]Haukeland University Hospital, Bergen, Norway, [2]Molecular and Cellular Neuroscience Department, Dorris Neuroscience Center, The Scripps Research Institute, La Jolla, CA, United States, [3]Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, United States, [4]Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Mechanotransduction, the pathway by which mechanical forces are translated to biological signals, plays important but poorly characterized roles in physiology. PIEZOs are recently identified widely-expressed mechanically-activated ion channels that are hypothesized to play a role in mechanotransduction in mammals.

Here, we describe two distinct PIEZO2 mutations in patients with Distal Arthrogryposis Type 5 (DA5), a generalized autosomal dominant contracture syndrome with limited eye movements, restrictive lung disease and variable absence of cruciate knee ligaments. Electrophysiological studies reveal that the two PIEZO2 mutations affect biophysical properties related to channel inactivation: both del2727E and I802F mutations cause the PIEZO2-dependent mechanically-activated currents to recover faster from inactivation, while del2727E also causes a slowing of inactivation. Both types of changes in kinetics result in increased channel activity in response to a given mechanical stimulus, indicating that DA5 is caused by gain-of-function mutations in PIEZO2. We further show that overexpression of mutated PIEZO2 cDNAs does not cause constitutive activity or toxicity to cells, arguing that the observed phenotype is likely to be a mechanotransduction defect.

Our studies identify a new type of channelopathy and link the dysfunction of mechanically activated ion channels to developmental malformations and joint contractures. We are presently sequencing PIEZO2 in other patients with sporadic or familiar arthrogryposis of a compatible phenotype.

Defective initiation of glycosaminoglycan synthesis due to mutations in B3GALT6 causes a pleiotropic connective tissue disorder with severe alterations in proteoglycan assembly and collagen fibrillogenesis

F. Malfait[1], *A. Kariminejad*[2], *T. Van Damme*[1], *C. Gauche*[3], *D. Syx*[1], *F. Mehri-Soussi*[3], *S. Gulberti*[3], *S. Symoens*[1], *S. Van Hauwaert*[1], *B. Bozorgmehr*[2], *M. Kariminejad*[2], *I. Hausser*[4], *A. Huysseune*[5], *S. Fournel-Gigleux*[3], *A. De Paepe*[1];

[1]Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium, [2]Kariminejad-Najmabadi Pathology & Genetics Center, Tehran, Islamic Republic of Iran, [3]UMR 7365 CNRS-Université de Lorraine (IMoPA) MolCelTEG Team, Biopôle UL - Faculté de Médecine, Campus Biologie-Santé, Vandoeuvre-lès-Nancy, France, [4]Department of Dermatology, University of Heidelberg, Heidelberg, Germany, [5]Biology Department, Ghent University, Ghent, Belgium.

Proteoglycans are very important components of cell plasma membranes and extracellular matrices of connective tissues. They consist of glycosaminoglycan chains attached to a core protein via a tetrasaccharide linkage, whereby the addition of the third residue is catalyzed by galactosyltransferase II (β3GalT6), encoded by B3GALT6. We identified biallelic B3GALT6 mutations in three families presenting a severe autosomal recessive connective tissue disorder, characterized by skin fragility, delayed wound healing, joint hyperlaxity and contractures, muscle hypotonia, mental retardation and a spondyloepimetaphyseal dysplasia with bone fragility and severe kyphoscoliosis. The phenotype strongly overlaps with several recessive Ehlers-Danlos variants and spondyloepimetaphyseal dysplasia with joint hyperlaxity. Homozygosity mapping and candidate gene sequence analysis identified homozygous B3GALT6 missense mutations in Family 1 (p.(Asp207His) and Family 3 (p.(Gly217Ser)), and compound heterozygous mutations in Family 2 (p.(Ala108Glyfs*163) and p.(Asp207His)). A strong decrease in ability to prime glycosaminoglycan synthesis was observed in patient's fibroblasts, confirming β3GalT6 loss-of-function together with impaired synthesis and glycanation of the small chondroitin/dermatan sulfate proteoglycan decorin. Dermal electron microcopy disclosed abnormal collagen fibril organization, in line with the important regulatory role of decorin in this process. A strong reduction in heparan sulfate was also observed, indicating that β3GalT6 deficiency impairs synthesis of both types of glycosaminoglycans. In vitro wound healing assay revealed significant delay, pointing to a role for glycosaminoglycan defect in impaired wound repair in vivo. Our findings uncover a novel genetic deficiency affecting glycosaminoglycan synthesis and emphasize a crucial role for β3GalT6 in a wide range of developmental and biological processes.

Opsismodysplasia (OPS) is a severe autosomal-recessive chondrodysplasia characterized by pre- and postnatal micromelia and extremely short hands and feet. The main radiological features are severe platyspondyly, squared metacarpals, delayed skeletal ossification, and metaphyseal cupping. In order to identify mutations causing OPS, a total of 19 cases from 12 unrelated families were included in this study. We performed exome sequencing in three cases from three unrelated families and only one gene was found to harbor mutations in all three cases, namely INPPL1 (inositol polyphosphate phosphatase-like 1). Screening INPPL1 in the remaining cases identified a total of 16 distinct mutations. Among the 19 cases, prenatal findings led to early termination of pregnancies (especially in recurrent sibs) in 10/19 cases and hygroma, short long bones, short extremities and narrow thorax were consistently observed. Four children died early (stillborn 30 WG- 15 months of age). The five remaining cases (3 to 19 years old), had normal cognitive development, severe short stature (below- 4 SDS), lower limb deformity and severe scoliosis with atlanto axial instability. Most mutations (8/16) resulted in premature stop codons, located in the catalytic domain, 5-phosphatase. INPPL1 belongs to the inositol-1,4,5-trisphosphate 5-phosphatase family, that govern a plethora of cellular functions by regulating the levels of specific phosphoinositides.
Our finding of INPPL1 mutations in OPS, a severe spondylodysplastic dysplasia with major growth plate disorganization, supports a key and specific role of this enzyme in endochondral ossification.

Hereditary spastic paraplegias are heterogeneous neurological disorders. At least 50 loci and 30 genes can account for these diseases. Whole genome linkage mapping in 2 HSP families originating from Spain and Tunisia allowed us to restrict the candidate interval of the SPG26 locus from 34 to 9 Mb. Capture and whole exome sequencing were then performed in patients from the two linked kindreds and from 3 other autosomal recessive HSP families with German, Portuguese and Brazilian origins. Focused analysis to the SPG26 candidate region, identified 3 truncating and 2 missense mutations segregating at the homozygous state in patients from all families in a gene encoding an enzyme of the lipid metabolism. Three additional truncating mutations were then found in two French isolated cases by direct Sanger sequencing of all coding exons of this novel HSP-related gene. All mutations were absent in large series of healthy unrelated controls. Patients (n=18) presented with an early onset spastic paraplegia preceded by mental impairment in most cases and complicated by the association of cerebellar ataxia and peripheral neuropathy with cortical atrophy at brain MRI. These findings highlight lipid metabolism in HSP, paving the way for a better understanding of the mechanisms involved in these diseases.

Neurodegeneration with brain iron accumulation (NBIA) comprises a group of monogenic disorders characterized by extensive iron deposition in the basal ganglia. Several subtypes can be distinguished based on clinical findings and neuroimaging features.
An exome sequencing approach applied to a clinically preselected group of 14 index cases identified *de novo* mutations in X-chromosomal *WDR45* in 13 of them. The associated phenotype includes early-onset global developmental delay and neurological deterioration in adulthood with parkinsonism, dystonia, and dementia. Brain MRI demonstrated marked iron deposition in the substantia nigra and globus pallidus. Of note, the phenotype of males and females is similar, an observation not yet fully understood but potentially explained by somatic mosaicism in males or patterns of skewed X chromosome inactivation in females.
WDR45 is a beta-propeller scaffold protein and plays a putative role in autophagy, possibly via interaction with ATG2A and ATG2B.
Histopathological and cellular studies are ongoing to further substantiate this hypothesis.

Severe congenital primary microcephaly is a clinically and genetically heterogeneous disorder. Currently, 10 disease causing genes have been described. These genes alter three main pathways leading to microcephaly: centrosome function, DNA repair and cell cycle regulation. Whole exome sequencing identified a novel co-segregating truncating mutation c.5335 C->T, p.R1779* towards the C-terminus of WDR81 in 5 affected siblings of a large consanguineous Turkish family with primary microcephaly. The same stop mutation in WDR81 was identified in another Turkish case with microcephaly. A missense mutation in WDR81 was described by (Gulsuner et al., 2011) to cause cerebellar hypoplasia only. We observed marked variability of the phenotype. All four females had extreme microcephaly with enlarged extra-axial spaces and ponto-cerebellar hypoplasia (MICaxPCH). One male had a simplified gyral pattern and cerebellar hypoplasia and another male fetus with hydrops fetalis had not yet developed late microcephaly (at 21 weeks of gestation). We created a zebrafish morpholino knock-out model of WDR81 which resembled the observed human microcephaly phenotype. Moreover, we observed in the zebrafish morpholino enlarged ventricles which are in analogy to the enlarged ventricles in the patients. WDR81 was highly expressed in the neocortex of human and mouse embryos by in situ hybridization and immunofluorescence. WDR81 was localised to the nucleus as shown by immunofluorescence and confirmed by western-blot of subcellular fractions. In summary, WDR81 mutations can cause microcephaly with variable penetrance. We propose that WDR81, as a nucleoplasmic protein, would be the first primary microcephaly protein not directly associated with the centrosome.

C13.4

Chromatin structure, transcription and CAG instability in Huntington's disease

*A. Goula[1], A. Stys[1], J. Chan[2], Y. Trottier[1], R. Festenstein[2], **K. Merienne**[1];*
[1]IGBMC, UMR 7104, Strasbourg, France, [2]Imperial college London, London, United Kingdom.

Expansion of CAG/CTG repeats is the causative mutation of many diseases, including Huntington's disease (HD) and myotonic dystrophy 1. These mutations are unstable in selective somatic tissues, which accelerates disease progression. The mechanisms underlying CAG/CTG repeat instability remain elusive. Here we investigated the relationship between chromatin structure, transcription and somatic CAG/CTG instability. We examined this hypothesis using the R6/1 and R6/2 HD mouse lines, which express a similar HD transgene. These mice present a similar HD-like pathology, though progression of the disease is fastest in R6/2 mice as compared to R6/1 mice. In the two mice, as in HD patients, somatic instability is high in the striatum, the tissue that preferentially degenerates, and low in the cerebellum, a tissue spared by the disease. However, the rate of CAG instability is increased in R6/2 tissues when compared to R6/1 matched-tissues. Our data indicate that an accessible chromatin structure and high transgene transcription underlie the high instability rates seen in R6/2 mice in comparison to R6/1 mice, but are not sufficient to explain tissue specificity of instability. Interestingly, the levels of RNA Pol II and histone mark associated with transcription elongation correlate with tissue-selective somatic CAG instability. Our data suggest that the dynamics of transcription at the HTT gene is differently regulated between the striatum and cerebellum, despite similar bulk levels of transgenic transcripts in the two tissues. We propose that the regulation of the transition from transcription initiation to transcription elongation is a mechanism contributing to tissue-selective CAG instability in HD.

C13.5

A large genomic deletion upstream of the lamin B1 gene (LMNB1) likely causes adult-onset autosomal dominant leukodystrophy due to alteration of the regulatory landscape of LMNB1.

***E. Giorgio**[1], D. Robyr[2], E. Di Gregorio[1,3], D. Lacerenza[1], G. Vaula[4], D. Imperiale[5], C. Atzori[5], A. Brusco[1,3], S. Antonarakis[2], A. Brussino[1];*
[1]University of Torino-Dep Medical Sciences, Torino, Italy, [2]University of Geneva Medical School, Department of Genetic Medicine and Development, Geneve, Switzerland, [3]A.O. Città della Salute e della Scienza, S.C.D.U. Medical Genetics, Torino, Italy, [4]A.O. Città della Salute e della Scienza, Department of Neurology, Torino, Italy, [5]Centro Regionale Malattie Da Prioni - Domp (Aslto2), Torino, Italy.

We report a position effect mutation in the lamin B1 locus mimicking Adult-onset Autosomal Dominant LeukoDystrophy (ADLD).
ADLD is a rare central nervous system demyelinating disease presently associated to *LMNB1* gene duplication. We collected a large Italian pedigree segregating an autosomal dominant form of leukodystrophy clinically overlapping ADLD. Linkage analysis mapped the disease to the LMNB1 locus, although *LMNB1* was not duplicated or mutated. However, *LMNB1* was overexpressed in fibroblasts both at mRNA and protein level as in reported ADLD patients. Using array-CGH analysis, we identified a 660 kb deletion located approximately 66 kb centromeric to the *LMNB1* gene and spanned three genes: *GRAMD3*, *ALDH7A1* and *PHAX*. shRNA silencing assays of these genes did not affect *LMNB1* expression. To search for non-coding regulatory elements, we performed circular chromosome conformation capture (4C) on fibroblasts from a patient and a control, using lamin B1 promoter as a bait. We identified four potential regulatory regions: one (region A) located within the deletion and shared by case and control, and three patient specific interactors (regions B, C and D) located upstream of the deletion. A dual-luciferase assay showed that regions A and B acted as enhancers (luciferase signal changes from 2.8 to 3.4 fold vs. control, respectively). Therefore, the presence of the deletion takes away region A and moves the cryptic enhancer B closer to the *LMNB1* gene in one allele, resulting in its overexpression and mimicking ADLD. Our results confirms that mutations in regulatory elements may be important determinants of Mendelian phenotypes.

C13.6

Interferon-beta induces clearance of mutant ataxin-7 and improves locomotion in SCA7 knock-in mice

***A. SITTLER**[1], A. Chort[1], S. Alves[1], M. Marinello[1], B. Dufresnois[1], J. Dornbierer[1], C. Tesson[1], M. Latouche[1], D. P. Baker[2], M. Barkats[3], K. El Hachimi[1], M. Ruberg[1], A. Janer[1], G. Stevanin[1], A. Brice[1];*
[1]CRICM_INSERM U975,CNRS 7225, UPMC, PARIS, France, [2]Biogen Idec, Cambrigde, MA, United States, [3]INSERM U 974, CNRS UMR 7215, UPMC, Myology inst., PARIS, France.

We showed previously, in a cell model of spinocerebellar ataxia SCA7 that interferon-beta induces the expression of promyelocytic leukemia protein (PML) and the formation of PML nuclear bodies that degrade mutant ataxin-7, suggesting that the cytokine, used to treat multiple sclerosis, might have therapeutic value in SCA7. We now show that interferon-beta also induces PML-dependent clearance of ataxin-7 in a preclinical model, SCA7266Q/5Q knock-in mice, and improves motor function. Interferon-beta, administered intraperitoneally three times a week, was internalized with its receptor in Purkinje and other cells and translocated to the nucleus. The treatment induced PML expression and the formation of PML nuclear bodies and decreased mutant ataxin-7 in neuronal intranuclear inclusions, the hallmark of the disease. No reactive gliosis or other signs of toxicity were observed in the brain or internal organs. The treatment also significantly improved the performance of the SCA7266Q/5Q knock-in mice on two behavioral tests sensitive to cerebellar function: the Locotronic test of locomotor function and the beam-walking test of balance, motor coordination and fine movements, which are affected in patients with SCA7. Finally, since neuronal death does not occur in the cerebellum of SCA7266Q/5Q mice, we showed in primary cell cultures expressing mutant ataxin-7 that interferon-beta treatment improves Purkinje cell survival. This treatment might apply to all polyglutamine diseases in which PML associates, in cell nuclei, with the mutant proteins responsible for the disease.

Purpose: Anophthalmia and microphthalmia (A/M) are early eye development anomalies resulting in absent or small ocular globes, respectively. A/Ms occur as syndromic or nonsyndromic forms. They are genetically heterogenous with some mutations in some genes responsible for both anophthalmia and microphthalmia. The purpose of this study was to identify the disease gene involved in A/M in an inbreed Pakistani Family.

Methods: A combination of homozygosity mapping, exome sequencing and Sanger sequencing, was used to identify the disease mutation in the Pakistani family and to screen the A3 isoform of the aldehyde dehydrogenase 1 (*ALDH1A3*) encoding gene for mutations in additional unrelated A/M patients.

Results: We identified homozygosity for a missense mutation in *ALDH1A3* in the Pakistani family. The screening of the gene is a cohort of A/M patients excluding known A/M genes allowed identifying two additional homozygote mutations including another missense change and a splice-site mutation in two consanguineous families. Patients with *ALDH1A3* mutations had A/M with occasional orbital cystic, neurological and cardiac anomalies.

Discussion and conclusion: ALDH1A3 is a key enzyme in the formation of a retinoic acid gradient along the dorso-ventral axis during the early eye development. Transitory expression of mutant *ALDH1A3* cDNAs showed that both missense mutations reduce the accumulation of the enzyme, potentially leading to altered retinoic acid synthesis. While the role of retinoic acid signaling in eye development is well established, our findings provide genetic evidence of a direct link between retinoic acid synthesis dysfunction and early eye development in human.

Introduction: Leber congenital amaurosis (LCA) is the earliest and most severe retinal dystrophy, responsible for neonatal blindness. In an effort to identify the yet unknown molecular bases of the disease, we subjected to whole exome resequencing (WER) the DNA of five unrelated families excluding known genes.

Methods and Results: Through WER combined with Sanger sequencing, we identified *NMNAT1* mutations in 22 unrelated LCA cases. *NMNAT1* codes for the ubiquitously expressed nuclear isoform of nicotinamide mononucleotide adenyltransferases. In addition to its NAD+ synthesizing activity, NMNAT1 acts as a chaperone that protects against neuronal activity-induced degeneration.

The review of ophthalmological data indicated that NMNAT1 mutations consistently caused LCA with a particular phenotype characterized by neonatal severe atrophy of the central retina leading to a posterior pole coloboma aspect and early-onset optic nerve atrophy.

These findings add further complexity to the physiopathological bases of the most common cause of blindness in childhood by giving support to the view that neuroprotection against light-induced stress is required to allow maintaining photoreceptor cells.

Conclusion: In summary, we report NMNAT1 mutations in 22 LCA families clinically recognizable by the existence of a neonatal macular atrophy and early-onset optic atrophy.

C14.3

Identification of new genes for Hereditary Hearing Loss (HHL) using linkage studies and Whole Exome Sequencing analysis

D. Vozzi[1], ***G. Girotto***[1], *F. Faletra*[1], *K. Abdulhadi*[2], *D. Vuckovic*[1], *A. D'Eustacchio*[1], *M. Khalifa Alkowari*[3], *R. Badii*[4], *P. Gasparini*[1];

[1]*IRCCS-Burlo Garofolo Children Hospital, Univ-Trieste, Trieste, Italy,* [2]*ENT Division HMC, DOHA, Qatar,* [3]*Mol. Gen. Lab., Doha, Qatar,* [4]*Mol. Gen. Lab, Doha, Qatar.*

Despite the presence of some major player genes for HHL, still there is a need to search for new causative mutations/genes. Whole Exome Sequencing (WES) coupled with linkage data (even if only suggestive loci) proved to be very useful in identifying 3 new HHL genes in a series of Italian and Qatari families. WES nucleotide variants were called by Samtools V0.1.18 and filtered comparing with in-house, dbSNP and 1000G databases. "*In silico*" functional prediction analysis of variants was done. Gene 1: in a recessive family from Qatar, linkage analysis identified 1 locus with a LOD of 3.8 on chromosome 5q13 subsequently confirmed by NGS with the presence of a mutation elongating the protein and segregating within the family (p.*2625Gluext*11) in BDP1 gene. This gene was also found as expressed in the mouse cochlea. Gene 2: linkage analysis in an Italian dominant family showed a LOD of 3.3 on chromosome 12q24. WES data of the region confirmed the presence of a missense mutation (c.1057G>C; pG353R) in P2X2 gene. A three-dimensional model of this protein, has also suggested that the substitution would destabilize the fold. Gene 3: an Italian Y-linked family was enrolled. Linkage analysis excluded autosomal loci while WES led to the identification of a missense mutation in a gene within DFNY1 locus. Functional *in vitro* studies are now in progress. Additional new HHL genes are under final validation steps in the remaining families. These findings increase our knowledge on molecular bases of HHL suggesting new targets for treatment and prevention

C14.4

A founder mutation in ULFIN, a new gene on chromosome 16q22.1, in patients with spinocerebellar ataxia type 4 (SCA4)

D. Braunholz[1], *F. Kähler*[1], *I. Braenne*[2], *Y. Hellenbroich*[1], *S. Tennstedt*[2], *P. Buse*[2], *P. Seibler*[3], *G. Gillessen-Kaesbach*[1], *J. Erdmann*[2], *C. Zühlke*[1], *F. Kaiser*[1];

[1]*Institut für Humangenetik Lübeck, Lübeck, Germany,* [2]*Institut für Integrative und Experimentelle Genomik, Lübeck, Germany,* [3]*Institut für Neurogenetik, Lübeck, Germany.*

SCA4 is an adult-onset neurodegenerative disorder with autosomal dominant inheritance, progressive ataxia, dysarthria and peripheral sensory neuropathy. The candidate region was mapped to an 8 Mb interval on chromosome 16q22.1 in two large families from Northern Germany. Since classical sequencing approaches of about 140 protein coding genes within this region could not reveal any obvious disease causing mutation, we performed whole genome sequencing analyses of one patient from each family.

By this, about 17500 variants were detected. After exclusion of known SNPs and selection based on conservation and putative regulatory function by using the public ENCODE-database, one variant was located within a transcription unit. This variant segregates with disease in both pedigrees and was found in another five unrelated patients with ataxia but excluded in >2500 controls from Northern Germany.

Interestingly, detailed *in silico* analyses as well as RNA analyses identified a hitherto unknown cDNA of 1712 bp encoding a 346 aa protein we named ULFIN. *ULFIN* codes for a WD40-repeat protein and is preferentially expressed in fetal and adult brain. The SCA4-variant identified causes the exchange of a highly conserved amino acid within a WD40 repeat domain. Protein modeling analysis demonstrated a significant conformational change caused by this missense mutation within this conserved structure.
In summary we identified a missense mutation in a so far unknown gene in two families and five unrelated patients with ataxia from Northern Germany. Our results indicate a founder effect as genetic cause of SCA4, a likewise frequent ataxia with ancestry in Northern Europe.

C14.5

U1 snRNP interference with polyadenylation - a new pathomechanism for unclassified 3'UTR mutations

J. Langemeier[1], *M. Radtke*[1], *C. Klein*[2], *J. Bohne*[1];
[1]*Hannover Medical School, Hannover, Germany,* [2]*Dr. von Haunersches Hospital, Munich, Germany.*

While most point mutations occurring in coding regions affect protein function or stability, mutations in regulatory regions are poorly understood. A point mutation in the 3' untranslated region (UTR) of the *p14/robld3* gene leads to a complex immunodeficiency syndrome characterized by albinism, short stature and a severe congenital neutropenia due to decreased protein and mRNA levels of the lysosomal scaffold protein p14. Investigation of the molecular pathomechanism revealed that the point mutation creates a functional 5' splice site (SS). Recognition by the spliceosomal component U1 snRNP, suppresses p14 mRNA expression in the absence of splicing. The extent of suppression correlates with the complementarity to U1 snRNA. P14 expression can be rescued by blocking U1 snRNP with modified antisense oligonucleotides.Although the precise mechanism of U1 snRNP-mediated suppression is not identified, we showed that U1 affects poly(A) site recognition. In our tandem poly(A) site (PAS) reporter system the 3' end processing machinery switches to the downstream PAS in the presence of the p14 mutation and in addition a substantial amount of read-through is produced indicating that U1 snRNP can inhibit two consecutive PAS. A similar 3'UTR mutation is also found in the factor IX gene resulting in hemophila B. We are currently investigating if this mutation found in 8 patients acts via the same pathomechanism as p14. Thus, 5'SS created by point mutations within 3' UTRs illustrate not only a novel mechanism for a primary immunodeficiency, but may also be at the base for other disorders characterized by defective mRNA biogenesis.

Staphylococcal infections are the cause of various diseases associated with a wide spectrum of symptoms and could range from benign to poor prognosis. S.epidermidis is an opportunist pathogen essentially responsible of nosocomial infections and has rarely been described as implicated in primary immunodeficiencies (PID).
We studied a patient from a consanguineous Indian family who suffered from upper respiratory tract infection and recurrent cellulitis to S. epidermidis, suggesting immune susceptibility. To identify the genetic defect, we associated genetic linkage analysis, exome sequencing, and a candidate gene approach. We identified an unreported homozygous variation in the patient. The gene encodes for a divalent cation/proton (Fe2+, Zn2+ and Mn2+) transporter. This mutation impairs protein expression in patient's granulocytes and induces a loss of function in terms of oxidative burst and Staphylococcus killing ability. Identical results were obtained using the PLB-985 granulocytes knock out for this protein. Thus, we identified a new genetic defect responsible of susceptibility to pyogenic bacterial infection, this help to delineate the important role of the NADPH pathway in bacterial immunity responses in granulocytes.

Neurosurgery Necker Hospital Paris, Paris, France,* [5]*Craniofacial Unit Dep. Neurosurgery Necker Hospital Paris, Paris, France.*

Fibroblast Growth Factor Receptor (FGFR) mutations are associated either to chondrodysplasia and craniosynostosis. In both conditions the growth of the skull base is altered. We analysed the extent of such alterations by CT scan in infants with a genetically confirmed mutation in FGFR and correlated them to the clinical phenotype.
The area of the Foramen Magnum (FM) was measured on CT scan obtained prior to any surgery in infants with FGFR mutation: Crouzon syndrome (FGFR2) n: 7, (mean age: 4.3m, 1 to 9), Pfeiffer syndrome (FGFR2) n:6 (mean age: 5.3 m; 3 to 11), Apert syndrome (FGFR2) n:9 (mean age: 5.8m, 3 to 7), Muenke-Lajeunie (FGFR3)n:16 (mean age: 5.6m, 3 to 8) , and achondroplasia (FGFR3) n: 4 (mean age 4.4m, 1-8) and compared to 30 controls (mean age: 4.7m, 0-12).
The FM size was reduced in all FGFR-related anomalies compared to controls (489.77 mm2) except for Apert syndrome (Crouzon: 346.39 mm2, $p<0.001$, Muenke-Lajeunie: 426.13mm2, $p<0.04$, Achondroplasia: 125.27 mm2, $p<0.001$, Pfeiffer: 383.78 mm2, $p<0.02$, Apert: 422.02 mm2, $p=0.07$). However, the extent of such alterations was extremely variable. The higher degree of reduction was found in achondroplasia whereas the milder degree was that of Apert patients. Smaller FM were associated to cerebrospinal fluid disorders (Subarachnoid or ventricular dilatations).
In conclusion, the large spectrum of FM alterations associated to FGFR mutations is associated to the type of gene mutation. The size of the FM seems to play a role in the occurrence of cerebrospinal fluid disorders disorders.

Purpose: The majority of epilepsies are focal in origin, with seizures arising in one region of the brain. The aetiology of most cases of focal epilepsy remains unknown and has not generally been thought to be genetic. We studied large pedigrees with forms of focal epilepsy (NFLE and FFEVF) which showed autosomal dominant (AD) inheritance to identify the genes responsible and then studied their broader contribution to the focal epilepsies.
Method: We used a strategy of whole genome linkage analysis followed by whole exome sequencing in two families with FFEVF mapping to Chromosome 22q12 and one large family with ADNFLE mapping to 9q34.3.
Results: We detected mutations in DEPDC5 in the two families and subsequently in 5/6 additional families with FFEVF. Furthermore, we found DEPDC5 mutations in approximately 12% (10/82) of families with non-lesional focal epilepsy. A mutation in the potassium channel gene KCNT1 was identified in the family with NFLE and subsequently in three other families with NFLE. Mutation-positive family members were also affected with psychiatric features, intellectual disability or autism spectrum disorders.
Conclusions: Mutations in DEPDC5 account for approximately 12% of cases of non-lesional familial focal epilepsy, becoming the most common known cause of familial focal epilepsy. KCNT1 mutations contribute to nocturnal frontal lobe epilepsy (NFLE) as well as to psychiatric features. Genetic factors therefore play an increasing role in the focal epilepsies. These findings enable improved patient diagnoses and reveal new pathways involved in the

pathogenesis of the focal epilepsies and related disorders.

C15.3

Targeted sequencing of GPI anchor synthesis pathway genes identifies mutations in PGAP2 as a new cause of hyperphosphatasia with mental retardation

P. M. Krawitz[1], *Y. Murakami*[2], *A. Rieß*[3], *M. Hietala*[4], *U. Krüger*[1], *Z. Na*[1], *T. Kinoshita*[2], *S. Mundlos*[1], *P. N. Robinson*[1], *J. Hecht*[1], *D. Horn*[1];
[1]*Medical Genetics and Human Genetics, Berlin, Germany,* [2]*Department of Immunoregulation, Osaka, Japan,* [3]*Human Genetics, Tübingen, Germany,* [4]*Medical Biochemistry, Turku, Finland.*

Recently, mutations in genes involved in the biosynthesis of the glycosylphosphatidylinositol (GPI) anchor have been identified in a new subclass of congenital disorders of glycosylation with a distinct spectrum of clinical features. To date mutations have been identified in six genes of the GPI-anchor synthesis pathway, PIGA, PIGL, PIGM, PIGN, PIGO, and PIGV in patients with severe neurological features including seizures, muscular hypotonia, and intellectual disability. We developed a diagnostic gene panel for targeting all known genes of the GPI-anchor synthesis pathway to screen patients matching these features, and detected three missense mutations in PGAP2, c.46C>T, c.380T>C, and c.479C>T, in two unrelated patients with hyperphosphatasia mental retardation syndrome (HPMRS). The mutations cosegregated in the investigated families. PGAP2 is a gene involved in fatty acid remodeling of the GPI-anchor, which occurs in the Golgi apparatus and is required for stable association of GPI-anchored proteins with the cell surface membrane rafts. Transfection of the mutant constructs p.Arg16Trp, p.Leu127Ser, and p.Thr160Ile into PGAP2-null cells showed only partial restoration of GPI-anchored marker proteins, CD55 and CD59, on the cell surface. In this work we show that also an impairment of GPI-anchor remodeling causes HPMRS and conclude that targeted sequencing of the GPI-anchor pathway genes is an effective diagnostic approach for this subclass of congenital disorders of glycosylation.

Consanguinity increases the risk for autosomal recessive (AR) disorders. Exome sequencing provides an opportunity to arrive at a molecular diagnosis in a proportion of unresolved phenotypes in these families, thereby identifying novel candidate genes for AR phenotypes. Samples were collected from 32 consanguineous families characterized by a wide spectrum of phenotypes suggestive of AR inheritance. DNA was taken from the patient(s), all unaffected siblings and parents. All samples were genotyped with 720K SNP array to identify Runs of Homozygosity, allowing the definition of identical-by-descent chromosomal regions likely to contain the responsible pathogenic variants. Exome sequencing was performed on one affected individual per family. Variants within the identified target areas were called and filtered for various criteria for pathogenicity. Samples from one affected individual per family were also examined by aCGH to detect homozygous deletions and duplications. On average, 21,719 variants were identified per patient. The putative pathogenic variant was found in known disease-causing genes (VLDLR, DMP1, FKTN, SEPSECS, GUCY2D, BBS4, SYNE1 and POMGNT1) in 8 families. In two families, strong candidate mutations were identified and in a further 16 families, variants of likely pathogenicity were found. In 6 families, no plausible candidates were identified. Consanguineous families provide a unique opportunity to identify pathogenic variants in both known and candidate genes responsible for recessive phenotypes in order to populate the missing space of genotype-to-phenotype links. We identified a putative causative variant in 25% of families tested. High-throughput sequencing represents a substantial improvement in our ability to diagnose recessively inherited disorders.

Background: Non-motile cilia are hair like structures extending from the surface of most cells in mammalian organisms. Mutations in genes encoding for cilia associated proteins lead to complex developmental defects and although individual ciliopathy diseases are very rare, together they represent a significant disease burden. Due to extensive genetic heterogeneity and phenotypic as well as genetic overlap, molecular diagnosis using Sanger sequencing has been proven very difficult in the past. However, the development of Next Generation Sequencing techniques such as Whole Exome Sequencing (WES) offers new diagnostic tools. **Results:** We have investigated 61 Jeune Asphyxiating Thoracic Dysplasia (JATD), 37 Bardet-Biedl-Syndrome (BBS), 7 Joubert and 9 other ciliopathy cases (total of 113 cases) using WES and were able to identify the disease causing gene in approximately two thirds of all cases with about 50% of JATD and Joubert cases but up to 90% of BBS cases being caused by known disease causing genes. Our findings lead to revision of the clinical diagnosis in some cases and revealed new phenotype-genotype associations, especially in JATD. Functional studies for several new genes identified are currently under investigation. However, the proportion of solved cases was much lower among less well defined phenotypes. **Summary:** Our findings in this large non-motile ciliopathy cohort demonstrate that WES is a very efficient tool in genetics diagnosis of heterogenous recessive disorders facilitated by deep phenotyping. Compared to NGS gene panel sequencing, WES offers additional opportunities to identify new genes previously not associated with the condition investigated.

Copy number variation (CNV) is a common source of genetic variation that has been implicated in many genomic disorders. This has resulted in the widespread application of genomic microarrays as a first tier diagnostic tool. More recently whole exome sequencing (WES) has proven highly successful for unbiased detection of clinically relevant point mutations and small insertion-deletions. Here, we evaluated the clinical utility of WES to detect CNVs in a set of DNAs from 10 patients with intellectual disability in which diagnostic SNP arrays previously detected 12 pathogenic CNVs. WES read depth approaches were compared to CNV detection provided by a range of (ultra) high-resolution microarrays (250K, 2.7M and 4.2M (exon targeted)), to assess WES performance. Using WES read depth data, we detected 11 of the 12 clinically relevant CNVs; a heterozygous single-exon deletion remained undetected. WES identified an average of five CNVs per exome, encompassing on average 8 genes (1-118). Breakpoint and gene content analysis showed that even though WES lacks breakpoint accuracy compared to the high-resolution microarrays, the gene content of clinically relevant CNVs, encompassing 3 or more exons, can be determined reliably. The detection power of WES for small and single-exon CNVs currently does not match the detection power of high-resolution microarray platforms, and should be optimized to detect these. The majority (76%) of all 33 rare coding CNVs (≥3 exons), identified by two independent microarray platforms, were successfully identified by WES making it even more attractive as a first tier diagnostic tool in genetically heterogeneous disorders.

Hirschsprung disease (HSCR, aganglionic megacolon; 1 in 5000 live births) is a disorder of the enteric nervous system (ENS) characterized by the absence of enteric neurons along a variable length of the intestine. HSCR most commonly presents sporadically, although it can be familial (5-20% of the patients). The sporadic

form of the disorder is believed to be a genetically complex disease with both *de novo* and/or inherited genetic lesions. To assess the role of *de novo* mutations (DNM) in sporadic HSCR, we performed exome sequencing on 16 HSCR patients and their unaffected parents. Standard BWA/GATK pipeline was used to map the sequence reads to human reference genome 19 and call genomic variants for all 48 samples simultaneously. Exonic DNM mutations were identified using KGGSeq. DNM candidates were scrutinized using Integrative Genomics Viewer (IGV) and those variants deemed plausible were validated by Sanger sequencing. In total we confirmed 20 *DNM* mutations (17 SNVs, 3 Indels) in 16 genes. Five DNM were identified in RET (major HSCR gene). CCR2, COL6A3, MED26, NUP98, HMCN1 and DENND3 had *DNM* mutations and were found mutated in independent HSCR patients. Importantly, some of these genes are members of pathways involved in the development of the ENS and the encoded proteins interact with known key signaling molecules. The overall exonic DNM mutation rate is 1.25 per HSCR trio, with 10 out of 16 (62.5%) patients harboring ≥ 1 DNM mutations. Therefore, DNM mutations, as inherited mutations, contribute to the development of sporadic HSCR.

C16.2

A novel chromosomal breakage syndrome caused by a missense mutation in a gene from the SMC5/6 complex

M. Harakalova[1], *S. N. van der Crabben*[1], *M. P. Hennus*[2], *J. M. van Montfrans*[3], *I. Renkens*[1], *K. Duran*[1], *M. van Roosmalen*[1], *S. van Lieshout*[1], *P. M. van Hasselt*[4], *S. W. We characterized two Caucasian sisters who died at the age of one year of a sudden progressive pulmonary deterioration with multiple viral infections despite an intact immune system. They showed failure to thrive, hypotonia, mild psychomotor retardation, eczema, sparse hair growth, prominent veins, multiple aspecific cerebral calcifications and allergy. Karyotyping in cultured lymphocytes showed up to two supernumerary marker chromosomes in the first girl and up to eight supernumerary marker chromosomes and missing chromosomal parts in the second girl. Array-CGH at 180K resolution based on DNA from blood of both sisters showed a normal female profile. Cultured skin fibroblasts grow very poorly; survivors show no chromosomal anomalies. All known chromosomal breakage syndromes were excluded by genetic testing.

Homozygosity mapping in the family revealed a large homozygous stretch of more than 8Mb and subsequent genealogical analysis proved consanguinity as far as ten generations back. Whole-exome sequencing in the two affected girls followed by additional segregation analysis in their healthy parents, two sisters and a brother identified a novel missense variant in a gene from the SMC5/6 complex proofing inheritance in an autosomal recessive manner. The missense variant overlaps with the largest homozygous stretch, is located in a conserved region, and predicted to have a damaging effect on the protein function by PolyPhen and SIFT. It is absent in all available databases.

This work suggests the first evidence of a germline mutation in a gene from the structural maintenance of chromosomes complex SMC5/6 linked to a novel chromosomal breakage syndrome.

Syndromes with signs of premature aging affecting several tissues are crucial to identify novel genes and pathways involved in the aging process. We have studied a consanguineous patient affected by a segmental progeroid syndrome with chromosomal instability and early-onset hepatocellular carcinoma. Exome sequencing revealed just a single non-annotated homozygous sequence change with a severe impact on protein structure: a homozygous frame-shift mutation in a formerly uncharacterized gene SPRTN. We showed that this protein is recruited to sites of DNA damage after treatment with genotoxic agents and is crucially involved in various DNA damage response pathways. siRNA-mediated depletion in cultured cells resulted in both severe

proliferation defects and chromosomal instability with increased sensitivity towards genotoxic agents comparable to the findings in patients' primary cells. We also observed a siRNA-mediated distortion of the nuclear envelope like seen in other types of segmental progeria, which could be rescued by expression of human wildtype but not by a construct expressing the mutant isoform. In addition, we cloned the zebrafish ortholog and could show that morpholino-based silencing resulted in an increase of γH2AX foci, as a marker of DNA damage, as well as in developmental defects and increased mortality. The latter could be partially rescued by expression of human wildtype but not by a construct expressing the mutant protein. In summary, we identified the cause of a novel segmental progeroid syndrome and a crucial role of this formerly uncharacterized gene in the regulation of aging.

CdLS is a rare multisystem genetic disorder typified by characteristic facies, prenatal onset growth failure, intellectual disability, distal limb anomalies, gastrointestinal and neurological disease. The phenotype shows a broad range of variability. About half of patients have mutations in *NIPBL*, which encodes a cohesin-associated factor. An additional 5% of the patients have mutations in *SMC1A* or *SMC3*, which encode structural components of cohesin. Loose genotype-phenotype correlations exist, with mutations in *NIPBL* resulting in the majority of the "classically" affected patients. However atypical or variant CdLS cases have a much lower mutation detection rate. Here we demonstrate that mutations in the X chromosome gene *HDAC8* are present in about 5% of our patient cohort and cause a recognizable subgroup of CdLS-like phenotypes. Most of these mutations are missense and *de novo*. About two-thirds of affected cases are heterozygous females and marked skewing of X-inactivation in peripheral blood DNA is common. Hemizygous males are more severely affected than females. The craniofacial appearance of *HDAC8*-cases is distinct from classical CdLS, and delayed anterior fontanelle closure may be a useful discriminating feature. Limb malformations appear to be rare and postnatal growth failure is less severe than classical CdLS. Functional analysis of mutant HDAC8 proteins demonstrates partial or complete loss function. These data demonstrate that mutations in *HDAC8* cause a clinically distinct subgroup of CdLS and solidify HDAC8-mediated deacetylation in the molecular mechanism in cohesin function.

Primary cilia are microtubule-based organelles whose formation and compartmentalization are ensured by selective import of specific cargoes through a barrier at the ciliary base. Given the structural constraints imposed by this selectivity barrier, how membrane-associated proteins are imported into the primary cilia has remained unclear. In a consanguineous family with Joubert Syndrome (JS), combined exome sequencing and mapping identified a homozygous splice site mutation in PDE6D, encoding a prenyl-binding protein. We found that pde6d depletion in zebrafish leads to renal and retinal developmental anomalies and that wild type but not mutant PDE6D is able to rescue this phenotype. In an effort to understand the pathophysiological mechanisms underlying PDE6D mutation in JS we used tandem affinity purification/mass spectrometry and identified the ciliary farnesylated protein INPP5E involved in two ciliopathies (Joubert and MORM syndromes) as a cargo of PDE6D. We showed that PDE6D binds to INPP5E in a farnesyl-dependent manner and that patient truncated PDE6D, which localizes properly to the basal body, shows reduced binding to INPP5E and to ARL2 and ARL3 that act as cargo-release factors for PDE6D-bound farnesylated proteins. In patients and PDE6D-depleted cells, INPP5E fails to localize to the primary cilia indicating that PDE6D is required for INPP5E ciliary targeting. This study provides the first evidence of prenyl-binding dependent trafficking in ciliopathies and highlights a specific mechanism enabling prenylated protein import within primary cilia.

C16.6

Integrator Complex Subunit 8 mutations associated with abnormal brain development and spliceosomal defect

R. Oegema, *R. Schot, D. Heijsman, L. van Unen, S. Kheradmand Kia, J. Hoogeboom, A. Kremer, F. W. Verheijen, P. van der Spek, R. Hofstra, M. Fornerod, G. M. S. Mancini; ErasmusMC, Rotterdam, Netherlands.*

The Integrator Complex (IC) is responsible for the 3'-end processing of the U1/U2 major spliceosome snRNAs. Maturation of these snRNAs presumably takes place in the subnuclear Cajal body and the IC is an essential component for its integrity. There is accumulating evidence that the IC is necessary for normal vertebrate development, however no association with human disease has been reported yet.
Three siblings presented with severe developmental brain abnormalities, cerebellar hypoplasia and periventricular nodular heterotopia (PNH) of unknown cause. Using whole genome sequencing (Complete Genomics), and filtering for recessive inheritance, we discovered compound heterozygous mutations in *Integrator Complex Subunit 8* (*INTS8*) in the three sibs, the parents being heterozygous. QRT-PCR showed 2-fold decreased *INTS8* RNA levels in patients' cells compared to controls. Pathway analysis (Ingenuity) of expression data (Affymetrix U133 expression arrays and Gene Chip 1.0 ST exon arrays) of RNA extracted from patient fibroblasts showed enrichment of deregulated genes involved in mRNA splicing and posttranscriptional modification. Expression data of (developing) human brain structures (Allen Brain Atlas) show that expression of *INTS8* peaks prenatally, especially in the ganglionic eminences, (sub)ventricular zone and hindbrain, similar to mouse embryo (Emage databse). From these areas neuronal precursors migrate to the cortex, and these regions are compatible with the PNH and cerebellar phenotype in the patients. Immuno-staining of Cajal bodies in *INTS8*-depleted and in patients' fibroblasts is ongoing and will be presented.
We propose that dysfunction of the Integrator Complex, through a spliceosomal defect, leads to severely disrupted brain development in humans.

C17.1

Natural variation in the histone demethylase, KDM4C, influences transcriptional regulation and cell growth

B. L. Gregory[1], *V. G. Cheung*[1,2];
[1]*University of Pennsylvania, Philadelphia, PA, United States,* [2]*Howard Hughes Medical Institute, Chevy Chase, MD, United States.*

Histone demethylases are chromatin modifiers; while their biochemical activities have been characterized, very few of their target genes are known.

In this study, by genetic and molecular analyses, we identified and characterized over 300 target genes of KDM4C, a member of the Jumonji family of histone demethylases. KDM4C demethylates tri-methylated H3K9 histone marks, which are associated with transcriptional repression.
We measured gene expression in B-cells from members of 45 large pedigrees, and treated gene expression levels as quantitative traits in linkage and association analyses. We found extensive individual variation in the expression level of *KDM4C*. Genetic analyses showed that *KDM4C* expression is regulated in *cis* by variants near the 3' end of *KDM4C*, and luciferase reporter assays confirmed the presence of enhancer activity in this region. The genetic studies also identified more than 300 genes whose expression levels are regulated by KDM4C. By chromatin immunoprecipitation, we found that KDM4C localized to these genes. Individuals with high *KDM4C* expression had more KDM4C binding to its target genes than individuals with lower *KDM4C* expression. Many of the target genes play key roles in cell proliferation. We found that cells from individuals with high *KDM4C* expression grew faster than those from individuals with lower *KDM4C* expression. In addition, we found *KDM4C* to be expressed at higher levels in cancers than in corresponding normal cells, and that KDM4C depletion attenuates cancer cell growth. In this presentation, I will describe how transcriptional regulation by KDM4C differs among individuals and how this influences cell growth.

C17.2

Enrichment of uniparental disomy events detected in the Deciphering Developmental Disorders rare disease study

D. A. King, *M. E. Hurles;*
Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

The Deciphering Developmental Disorders (DDD) project aims to identify the disease-causing mutations for 12,000 children in the UK with rare, presumed genetic, developmental diseases. This study uses a proband-mother-father trio design, which by its nature facilitates the identification of inheritance anomalies. This work focuses on the investigation of uniparental disomy (UPD), an inheritance defect characterised by the inheritance of both chromosome homologs from only one parent. UPD can result in imprinting disorders, or lead to the unmasking of recessive disorders, phenomena that are generally uncommon, but over-represented among individuals with rare diseases. Our newly developed method reads VCF-formatted trio genotype data, identifies genotypes in the proband only compatible with uniparental inheritance, and performs a statistical test to identify chromosomes with a significant enrichment of these informative genotypes. Simulation testing demonstrated 100% sensitivity in detecting whole-chromosome UPD events from both SNP genotyping chip-derived and exome-derived genotypes, and remained completely sensitive for segmental UPD detection down to ten megabases for most types of UPD. We applied the method on 1,075 trios from the DDD project and identified five probands with complete chromosomal uniparental disomy and one proband with segmental uniparental disomy. This is a significant enrichment over the population prevalence of UPD, suggesting that most of these events are pathogenic. One of these events represents a known imprinting disorder and exome analysis has identified several rare homozygous candidate variants, mainly in the isodisomic regions of UPD chromosomes, which provide targets for further functional evaluation.

C17.3

Exonic splicing mutations in Mendelian disorders: more prevalent than currently estimated

O. Soukarieh[1], D. Di Giacomo[1], S. Krieger[2], T. Frébourg[1,3], M. Tosi[1], P. Gaildrat[1], ***A. Martins***[1];
[1]*Inserm U1079, University of Rouen, Institute for Research and Innovation in Biomedicine, Rouen, France,* [2]*Cancer Genetics, CRLCC François Baclesse, Caen, France,* [3]*Department of Genetics, Rouen University Hospital, Rouen, France.*

The identification of a causal mutation is essential for molecular diagnosis and clinical management of Mendelian diseases. Even if new-generation exome sequencing has greatly improved the detection of exonic changes, the biological interpretation of most exonic variants remains challenging. We evaluated the prevalence of RNA splicing mutations among exonic variants identified in *BRCA2* and *MLH1*, two genes implicated in the most frequent Mendelian forms of cancer. *BRCA2* exon 7 and *MLH1* exon 10 were used as model systems. By performing minigene-based *ex vivo* assays, we determined the effect on splicing produced by all single-substitutions listed in public databases, within these exons, initially reported as synonymous, missense or nonsense mutations (n=52). Our results revealed that a significant fraction of these variants have an effect on splicing. Importantly, when patient RNA was available, minigene and *in vivo* data were shown to be concordant. Remarkably, a significant subset of variants induced exon skipping in spite of being located outside splice sites (10 in *BRCA2* and 7 in *MLH1*), an effect that could not be predicted by commonly used bioinformatic approaches. This observation led us to test a newly developed *in silico* tool aiming at detecting exonic splicing regulatory elements. With very few exceptions, we found the predictions produced by this tool to be concordant with our minigene-derived data. This study shows that the fraction of splicing mutations is underestimated in Mendelian diseases and highlights the predictive potential of a newly developed *in silico* tool in pinpointing exonic mutations that affect RNA splicing.

New insights into human germline chromothripsis: underlying mechanisms and definition

L. Nazaryan[1], *M. Bak[1], A. Lind-Thomsen[1], C. Halgren[1], E. Stefanou[2], C. Hansen[1], K. F. Henriksen[1], M. Bugge[1], J. Lespinasse[3], G. Houge[4], N. Tommerup[1];*
[1]*Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicin, University of Copenhagen, Copenhagen, Denmark,* [2]*Laboratory of Medical Genetics, Department of Pediatrics, University General Hospital of Patras, Rion, Greece,* [3]*Department of Cytogenetics, Central hospital, Chambery, France,* [4]*Center of Medical Genetics and Molecular Medicine, Bergen, Norway.*

Recently, a new phenomenon of highly complex genomic rearrangements was revealed, which was termed chromothripsis and defined by the accumulation of multiple breakpoints within relatively small chromosomal regions and by extensive rearrangements within a single cell cycle. So far there are only data from 13 reported germline chromothripsis (GC) cases with a maximum number of breakpoints < 25. The lower complexity has been suggested to be due to selection. Herein, we present five new cases of GC, two of which are the most complex cases studied so far, involving 46 and 140 breakpoints, respectively. This supports that viability of these cases is not determined by the number of breakpoints per se, but rather by the functional consequences of the truncated genes and regulatory landscapes. We confirmed the surprisingly balanced state of GC in four cases, but one is associated with larger deletions at all breakpoints involved. The most likely mechanism for these rearrangements would be local shattering of the chromosomal regions generating numerous double-strand DNA breaks, which have subsequently been repaired by non-homologous or microhomology-mediated end-joining mechanisms. However, we do not exclude the involvement of replication based mechanisms in the case with deletions at all breakpoints. Combined with the reported GC cases, we observe a significant overlap of the shattered chromosomal regions suggesting that the shattering may be a non-random process. Finally, we clarify the term chromothripsis and classify chromosome shattering as mild, moderate and severe based on the number of breakpoints accumulated within a cluster.

C17.5

Whole-genome sequencing analysis of human induced pluripotent stem cells uncovers lineage-manifested CNVs

A. E. Urban[1], *A. Abyzov[2], J. Mariani[2], D. Palejev[2], M. Haney[1], Y. Zhang[2], L. Tomasini[2], A. Szekely[2], S. M. Weissman[2], M. Gerstein[2], F. Vaccarino[2];*
[1]*Stanford University, Palo Alto, CA, United States,* [2]*Yale University, New Haven, CT, United States.*

We have performed whole-genome sequencing based CNV analysis in 7 fibroblast samples and 20 corresponding induced pluripotent stem cell lines obtained from two families [Abyzov et al., Nature. 2012 Dec 20;492(7429):438-42].
We found that on average an iPSC line has two LM-CNVs (lineage-manifested CNVs). We defined the term LM-CNV to describe CNVs detected by genome-wide analyses in an iPSC line but not in the fibroblast culture from which the given iPSC line was derived but without making a statement as to the nature of the CNV-forming event (i.e. *de novo* formation during reprogramming from fibroblast to iPSC or unmasking of a somatic variant present in mosaic fashion in the fibroblast tissue).
After detecting LM-CNVs by sequencing based analysis in the iPSC lines we investigated the masked, mosaic presence of the same CNVs in the fibroblast tissue of origin. We determined that more than half of the LM-CNVs detected

in iPSC lines were already present as low allele frequency, mosaic somatic CNVs in the fibroblasts and that up to 40% of fibroblast cells carry such medium-sized to large somatic CNVs. Therefore, *de novo* CNVs in iPSCs may not be an obligate consequence of reprogramming. Our analysis unexpectedly revealed extensive somatic copy number variability in fibroblasts carrying over into iPSC and becoming unmasked in the process.
Our results underline the necessity of carrying out high-resolution genome analysis during iPSC-model based studies and demonstrate that whole-genome sequencing allows for detection and managing of the potential confounds caused by genomic variation such as LM-CNVs.

C17.6

Modelling and rescuing neurodevelopmental defect of Down syndrome using induced pluripotent stem cells from monozygotic twins discordant for trisomy 21

Y. HIBAOUI[1,2], *I. GRAD*[1], *A. LETOURNEAU*[2], *M. R. SAILANI*[2], *S. DAHOUN*[2], *F. A. SANTONI*[2], *S. GIMELLI*[2], *M. L. GUIPPONI*[2], *M. PELTE*[3], *F. BENA*[2], *S. E. ANTONARAKIS*[2], *A. FEKI*[1,4];
[1]*Stem Cell Research Laboratory, Department of Obstetrics and Gynecology, Geneva University Hospitals, CH-1211 Geneva, Switzerland,* [2]*Department of Genetic Medicine and Development, University of Geneva Medical School and Geneva University Hospitals, CH-1211 Geneva, Switzerland,* [3]*Department of Pathology and Immunology, Faculty of Medicine, University of Geneva, CH-1211 Geneva, Switzerland,* [4]*Service de gynécologie obstétrique, HFR Fribourg - Hôpital cantonal, CH-1708 Fribourg, Switzerland.*

Down syndrome (DS, trisomy 21), is the most common chromosomal disorder, with an incidence of 1 in 800 live births. Its phenotypic characteristics include intellectual impairment and several other developmental abnormalities, for the majority of which the pathogenetic mechanisms remain unknown. Here, we have generated induced pluripotent stem cells (iPSCs) derived from monozygotic twins discordant for trisomy 21: Twin-N-iPSCs and Twin-DS-iPSCs. Since the rest of the genome is identical between the two samples, we hypothesize that these twins were ideal to study the effect of the supernumerary chromosome 21.
We found that Twin-DS-iPSCs recapitulate the neurodevelopmental features of DS. The alterations observed by genetic analysis at the iPSC level and at first approximation in early development illustrate the developmental disease transcriptional signature of DS. DS-iPSCs exhibited an abnormal neural differentiation *in vivo* and *in vitro*. Twin-DS-iPSC-derived neurospheres showed a reduced number of neuroprogenitor cells (NPCs). When NPCs were further differentiated into neurons, we found structural changes in the architecture and density of neuron, glial cell and oligodendrocyte populations together with misexpression of genes involved in lineage specification, neurogenesis and brain development. Importantly, targeting *DYRK1A* (on chromosome 21) pharmacologically or by shRNA corrected these defects. These improvements were associated with the restoration of *REST/NRSF*, *WNT* and *NOTCH* signaling to near normal levels.
In conclusion, these findings establish iPSCs generated from human monozygotic twins discordant for trisomy 21 as a unique model to recapitulate DS phenotypes, study the detailed mechanisms involved in the pathogenesis of DS and design new therapies.

Previous investigations by the Genetic Investigation of ANthropometric Traits (GIANT) consortium have shown that seven of the 14 single nucleotide polymorphisms (SNPs) found to influence body shape have significantly larger effect in women than in men. Adult body composition and body shape change over time (e.g. following menopause), which may be explained by age-and-sex-dependent genetic effects.
We conducted age-and-sex stratified genome-wide association (GWA) meta-analyses of 117 studies (133,012 women, 100,652 men) within the GIANT consortium. Each study tested for association of up to 2.8M SNPs and obesity related traits: body mass index (BMI) and waist-hip ratio (WHR). The effects were estimated separately in four strata divided by age (<50y, >=50y) and sex and subsequently compared against each other via heterogeneity test.
Our analysis identified no sex- and eight age-specific BMI associations at 5% FDR. Three novel BMI SNPs are located in or near PVRL2, TCF7L2 and DDC. The novel TCF7L2 association (observed in >=50y) is also linked to type 2 diabetes, however the effect direction is opposite. An additional five SNPs are located near established BMI loci: SEC16B, ADCY3, TNNI3K, TMEM18, NEGR1. Two out of the 8 SNPs have stronger effect in the older group. For WHR, we identified no age- and 29 sex-specific associations, 20 of which are novel loci. Strikingly, all but three SNPs have a more pronounced effect in women than in men.
Our results highlight the importance of sex- and age-stratified GWAS analyses in revealing the sex- and age-dependent genetic underpinnings of obesity traits.

Low vitamin D status is highly prevalent and associated with high blood pressure (BP) and hypertension in observational studies. We used a Mendelian Randomization approach to investigate the causal relationship between vitamin D status [measured by 25-hydroxyvitamin D, 25(OH)D] and BP/hypertension. We examined associations of four vitamin D-related SNPs with 25(OH)D (for validation) and with BP/hypertension (for causal inference) individually and in combination using separate allele scores for SNPs involved in synthesis (comprising DHCR7 and CYP2R1) and metabolism (comprising GC and CYP24A1) of 25(OH)D. Meta-analysis included up to 108,173 individuals from 35 studies. 25(OH)D was associated with systolic BP (SBP) (p=0.01) and hypertension (p=0.01). All four SNPs were strongly associated with 25(OH)D (p<7.59 x 10-14). None of the SNPs/allele scores was associated with BP/hypertension. However, when meta-analysing D-CarDia results together with results from International Consortium

for Blood Pressure to increase statistical power (n=125,172, overlapping studies excluded), both CYP2R1 (p=0.03) and synthesis score (p=0.01) were associated with DBP. Similarly, CYP2R1 (p=0.02) and synthesis score (p=0.002) showed an association with hypertension after meta-analysing D-CarDia results with results from CHARGE and Global BPgen consortia (n=150,846). Instrumental variable analyses using synthesis score as an instrument suggested a modest causal association, where for every 10% increase in 25(OH)D concentrations, there was a 0.24 mmHg decrease in DBP (95%CI:-0.43,-0.05,p=0.02) and 7% decrease in the odds of hypertension (95%CI:2.4%,11.1%,p=0.003). In conclusion, these data support a causal role of higher 25(OH)D in leading to reductions in blood pressure, providing further support for important non-skeletal effects for vitamin D.

C18.3

Large-scale genome-wide association meta-analysis using imputation from the dense 1000 Genomes Project identifies novel susceptibility loci for glycemic and obesity traits: ENGAGE Consortium report

M. Horikoshi[1], *R. Mägi*[2], *I. Surakka*[3], *A. Sarin*[3], *A. Mahajan*[1], *L. Marullo*[4], *T. Ferreira*[1], *T. Esko*[2,5], *C. M. Lindgren*[1,5], *A. P. Morris*[1], *M. I. McCarthy*[1,6], *S. Ripatti*[3,7], *I. Prokopenko*[8,1];
[1]*University of Oxford, Oxford, United Kingdom,* [2]*Estonian Genome Center, University of Tartu, Tartu, Estonia,* [3]*FIMM, University of Helsinki, Helsinki, Finland,* [4]*University of Ferrara, Ferrara, Italy,* [5]*Broad Institute, Cambridge, MA, United States,* [6]*Churchill Hospital, Oxford, United Kingdom,* [7]*Wellocme Trust Sanger Institute, Hinxton, United Kingdom,* [8]*Imperial College London, London, United Kingdom.*

Genome-wide association studies (GWAS) detected numerous associations with quantitative glycemic and obesity traits: only ~5% of phenotypic variance been explained mainly by common variants (minor allele frequency, MAF >5%). Our aim was to detect novel associated loci; low frequency variants influencing trait variability and novel independent variants at known loci. We performed large-scale fixed-effects meta-analysis of GWAS data including up to 38 million SNPs imputed using the 1000 Genomes Project reference panel (06/2011 release). The analysis was performed in up to 18 European GWAS, for fasting glucose (FG, n=46,694), fasting insulin (FI, n=24,245), body-mass-index (BMI, n=87,048) and waist-to-hip ratio adjusted for BMI (WHR, n=54,572).

We identified novel loci at genome-wide significance for FG (1 locus near *RMST*, p=2.0x10^{-10}, MAF=0.10) and BMI (5 loci near *GALNT10*, *DTX2P1*, *GRID1*, *EPYC* and *AKAP6*; p<4.5x10^{-8}, MAF=0.07~0.49). Through conditional analysis, we identified a novel low-frequency variant associated with FG independent of the lead SNP at *G6PC2* (2-169748691, MAF=0.012, p=3.0x10^{-19}, conditional p=1.7x10^{-21}). At a known locus for WHR, *RSPO3*, we detected a novel independent lead signal with stronger association and larger effect size than the previously reported signal (new β=0.11, p=1.7x10^{-13}, MAF=0.08 vs. old β=0.04, p=2.1x10^{-11}, MAF=0.49).

Our results highlight the potential advantages of imputation using the high-density reference panels for the identification of novel associated signals for both common and low frequency variants for quantitative metabolic traits.

Imputation of missing genotypes can be an effective method to improve genome-wide association studies (GWAS) by increasing the number of SNPs to be tested for association. By¬¬¬ matching the study haplotypes to high-resolution reference haplotypes, the imputation process is able to infer genotypes of un-typed variants. We show that the Genome of The Netherlands (GoNL) reference set not only outperforms the 1000 genomes (1000G) reference set for imputing Dutch samples but also for Italian samples. We also assessed the effect of fine-mapping on an eQTL study.

We quantified the difference in imputation quality by using samples genotyped on the Hap550 and the ImmunoChip, which we used as our gold standard. Genotypes from Hap550 were imputed using GoNL and 1000G to produce two datasets. The imputed genotypes were compared to genotypes present on the ImmunoChip. The median concordance in the Dutch samples of 4,192 rare SNPs (MAF <0.5%) increased from 0.37 to 0.54 when the imputing used GoNL compared to 1000G. In the Italian samples the median concordance of rare variants also improved when using GoNL (from 0.27 to 0.37). We found large deviations of the predicted concordance to the observed concordance, validating the use of our gold-standard benchmarking and making it evident that interesting imputed variants should always be validated.

An eQTL dataset was used to assess the effects of a better imputation on GWAS. We found a significant improvement when using imputation, both in signal strength and in fine-mapping. For the fine-mapping we performed an enrichment on ENCODE's regulomeDB.

Genome-wide assocation study identifies common variation associated with congenital heart disease

J. Goodship[1], *H. Cordell*[1], *J. Bentham*[2], *A. Topf*[1], *D. Zelenika*[3], *S. Heath*[3], *C. Mamasoula*[1], *D. Brook*[4], *S. Bhattacharya*[2], *D. Winlaw*[5], *K. Devriendt*[6], *S. Mital*[7], *A. Postma*[8], *M. Lathrop*[3], *M. Farrall*[2], *B. Keavney*[1];
[1]*Institute of Genetic Medicine, Newcastle upon Tyne, United Kingdom,* [2]*Department of Cardiovascular Medicine, Oxford, United Kingdom,* [3]*Centre National de Genotypage, Evry, France,* [4]*Institute of Genetics, Nottingham, United Kingdom,* [5]*The Children's Hospital, Westmead, Australia,* [6]*Centre for Human Genetics, Leuven, Belgium,* [7]*Hospital for Sick Children, Toronto, ON, Canada,* [8]*Academic Medical Centre, Amsterdam, Netherlands.*

We tested the hypothesis that common variants contribute to congenital heart disease by conducting a genome-wide association study for Tetralogy of Fallot (TOF) using a northern European discovery set of 835 cases and 5159 controls. A large region on chromosome 12q24 which includes *PTPN11* was associated (P = 1.4 × 10^{-7}) and replicated in 798 cases and 2931 controls (replication P = 3.9 × 10^{-5}; combined P = 7.7 × 10^{-11}). SNPs in *GPC5* on chromosome 13q32 were also associated (P = 1.7 × 10^{-7}) and replicated convincingly in 789 cases and 2927 controls (replication P = 1.2 × 10^{-5}; combined P = 3.03 × 10^{-11}). We extended the GWAS to a discovery cohort of 1,995 cases with various CHD phenotypes. A region on chromosome 4p16, between *MSX1* and *STX18*, was associated (P=9.5x10^{-7}) with the risk of atrial septal defect (ASD; N=340 cases), and this was replicated in a further 445 ASD cases and 2520 controls (replication P=1.1x10^{-4}; combined P=6.9x10^{-10}). The association between SNPs at 12q24 and TOF was not apparent in any other CHD subgroup; similarly, the association between SNPs at 4p16 and ASD was not apparent for CHD phenotypes other than ASD. We conclude that there is phenotypic specificity for common variants associated with CHD.

The Brugada Syndrome (BrS) is considered as a rare Mendelian disorder with autosomal dominant transmission. BrS is associated with an increased risk of sudden cardiac death and specific electrocardiographic features consisting of ST-segment elevation in the right precordial leads. Loss-of-function mutations in SCN5A, encoding the pore-forming subunit of the cardiac sodium channel (Nav1.5), are identified in ~20% of patients. However, studies in families harbouring mutations in SCN5A have demonstrated low disease penetrance and in some instances absence of the familial SCN5A mutation in some affected members. These observations suggest a more complex inheritance model.

To identify common genetic factors modulating disease risk, we conducted a genome-wide association study on 312 individuals with BrS and 1115 ancestry-matched controls. Two genomic regions displayed significant association. Replication testing on two independent case/control sets from Europe (598/855) and Japan (208/1016) confirmed both associations and revealed a third one. While two loci displaying association hits had already been shown to influence ECG parameters in the general population, the third one encompasses a transcription factor which had never been related to cardiac arrhythmia We showed that this factor regulates Nav1.5 channel expression in hearts of homozygous knockout embryos and influence cardiac conduction velocity in adult heterozygous mice. At last, we found that the cumulative effect of the 3 loci on disease susceptibility was unexpectedly large, indicating that common genetic variation may have a strong impact on predisposition to rare disease.

Insulin resistance (IR) is closely associated with many common, complex and multifactorial conditions. Identifying the genetic basis of rare monogenic forms of IR provides unique opportunities to decipher the molecular mechanisms underlying more prevalent forms. SHORT syndrome (Short stature, Hyperextensibility of joints and/or inguinal hernia, Ocular depression, Rieger abnormality, Teething delay) is characterized by the presence of lipodystrophy with generalized thin habitus despite normal food intake. Onset of IR and/or diabetes mellitus usually occur in adolescence. We studied eight families with SHORT syndrome using a combination of trio-based exome sequencing and capillary sequencing, and identified five *de novo* or inherited mutations of *PIK3R1* in all affected individuals. *PIK3R1* encodes the regulatory subunits of class IA phosphatidylinositol 3-kinases (PI3K), which play a key role in insulin signaling through binding of phosphorylated insulin receptor substrates and subsequent activation of AKT serine/threonine kinase. Multiple lines of evidence indicate that the *PIK3R1* mutations identified in individuals with SHORT syndrome should result in decreased PI3K/AKT signaling. Because growth hormone (GH) treatment is known to induce hyperinsulinemia and to decrease insulin sensitivity, a phenomenon that may aggravate IR and accelerate the onset of diabetes in subjects with SHORT syndrome, GH treatment was ceased in the patients treated. In conclusion, our findings highlight the critical role of *PIK3R1* in insulin action, normal growth and development. They also well illustrate the fact that novel genetic findings can have direct implications for patient care by enabling a more personalized clinical management.

Genome sequencing identifies mutations causing pancreatic agenesis in a novel *PTF1A* enhancer

S. Ellard[1], *M. N. Weedon*[1], *I. Cebola*[2], *A. Patch*[1], *E. de Franco*[1], *S. E. Flanagan*[1], *S. Rodriguez-Segui*[2], *J. A. L. Houghton*[1], *H. Lango Allen*[1], *C. Shaw-Smith*[1], *R. Caswell*[1], *A. Murray*[1], *P. Ravassard*[3], *L. Vallier*[4], *J. Ferrer*[5], *A. T. Hattersley*[1];

Mutations in non-coding regulatory elements are a rare cause of human disease. Genome sequencing promises to uncover disease causing mutations in novel regulatory elements, but as yet there are no reported successes using this approach.

We used a combination of genome sequencing and linkage in consanguineous pedigrees affected with isolated pancreatic agenesis. Homozygosity mapping revealed a shared region encompassing the *PTF1A* gene in which mutations are known to cause a rare syndrome of pancreatic agenesis and cerebellar hypoplasia. Sequencing of *PTF1A* and 31 other genes within the linkage interval failed to identify causative mutations.

Genome sequencing in two probands identified 6380 variants within the 7.6Mb shared homozygous region. The 193 novel variants included a base substitution affecting a highly conserved nucleotide (GERP score = 5.65) located within a ~400bp region of strong evolutionary conservation >20kb from the *PTF1A* gene. Four additional mutations and one large deletion spanning the element were identified in a total of 10 families.

Functional studies showed that the conserved element acts as an enhancer of *PTF1A* in human and mouse pancreatic progenitor cells. The enhancer binds transcription factors known to be critical for pancreatic development and the mutations abolish transcription factor binding.

Mutations in this novel enhancer are the most common cause of non-syndromic pancreatic agenesis in our cohort and these results provide new insights into the regulatory mechanisms underlying pancreatic development. To our knowledge, this is the first study to report the identification of pathogenic mutations in a novel regulatory element by genome sequencing.

Primary aldosteronism is present in up to 7% of hypertensive individuals. It is caused by bilateral adrenal hyperplasia or unilateral aldosterone-producing adenomas (APAs) in 50% of cases, each. Recent reports identified mutations in the potassium channel gene KCNJ5 as a cause of 30-40% of all APAs.

We sequenced additional APA-tumors without KCNJ5 mutations and matched control tissue from nine males. We identified recurrent mutations in two members of the P-type ATPase gene family, ATP1A1 (encoding an Na+/K+ ATPase) and ATP2B3 (encoding the plasma membrane Ca2+ ATPase).

All five identified alterations are either located in the transmembraneous α helix M1 or the juxtaposed α helix M4 in both ATP1A1 and ATP2B3. The recurrence of mutations affecting these highly conserved regions involved in interaction with the transported cations in two paralogs is suggestive of a gain-of-function effect.

We then investigated a collection of 309 APAs and found 16 (5.2%) somatic mutations in ATP1A1 and 5 (1.6%) in ATP2B3. Mutation-positive cases showed male dominance, increased plasma aldosterone concentrations and lower potassium concentrations compared with mutation-negative cases.

Functional in vitro studies of ATP1A1 mutants showed loss of pump activity and strongly reduced affinity for potassium. Electrophysiological ex vivo studies on primary adrenal adenoma cells provided evidence for inappropriate depolarization of cells with ATPase alterations.

In summary, dominant somatic alterations in two members of the ATPase gene family result in autonomous aldosterone secretion in roughly 7% of aldosterone-producing adenomas.

C19.4

Mutation-dependent recessive inheritance in NPHS2-associated steroid-resistant nephrotic syndrome. Beyond Mendel's laws

K. Tory[1,2,3], *D. K. Menyhárd*[4], *F. Nevo*[1,3,5], *O. Gribouval*[1,3,5], *A. Kerti*[2], *P. Stráner*[4], *C. Arrondel*[1,3,5], *T. Tulassay*[2,6], *G. Mollet*[1], *A. Perczel*[4], *C. Antignac*[1,3,5];

[1]*INSERM U983, Paris, France,* [2]*Ist Department of Pediatrics, Semmelweis University, Budapest, Hungary,* [3]*Institut Imagine, Paris, France,* [4]*MTA-ELTE Protein Modeling Research Group, Laboratory of Structural Chemistry and Biology, Budapest, Hungary,* [5]*Université Paris Descartes, Sorbonne Paris Cité, Paris, France,* [6]*Research Laboratory for Pediatrics and Nephrology, Hungarian Academy of Sciences and Semmelweis University, Budapest, Hungary.*

NPHS2, encoding the membrane-anchored podocin, is the most frequently mutated gene in steroid-resistant nephrotic syndrome (SRNS). Its mutations are inherited in an autosomal recessive fashion. While mutations on both alleles ([mut];[mut]) lead to early-onset SRNS, the trans-association of the polymorphism c.686G>A (p.Arg229Gln, rs61747728, MAF in Europeans: 3-4%) and a mutation ([p.Arg229Gln];[mut]) is known to cause late-onset SRNS.

As there is an important difference in the observed and the expected frequency of patients with [p.Arg229Gln];[mut], we hypothesized that [p.Arg229Gln];[mut] may not be pathogenic in all individuals. This was confirmed by the identification of [p.Arg229Gln];[mut] in 6/129 unaffected parents of children, who carried *NPHS2* mutations in exons 1-5. Interestingly, the mutations associated to p.Arg229Gln in affected patients are missense mutations of exons 7-8 in the majority of cases (56/71 alleles, 79%), though these mutations are rare in patients with [mut];[mut] (34/498 alleles, 7%, $p=1.4x10^{-39}$). This striking difference points to the pivotal role of the associated mutation in the pathogenicity of [p.Arg229Gln];[mut]. To understand their pathogenic association at a cellular level, we studied the subcellular localization of podocin^{Arg229Gln} in function of the associated mutation in cultured podocytes. Podocin^{Arg229Gln} was mislocalized only when co-expressed with podocins carrying the substitutions encoded by exons 7-8, but not with substitutions encoded by exons 1-6. Accordingly, a structural model of homodimerization supported that significant structural reorganization only appears in dimers of pathoghenic associations.

Here, we described for the first time an autosomal recessive disorder, in which the pathogenicity of the two alleles depends on each other.

Steroid-resistant nephrotic syndrome (SRNS) is a glomerular disorder with a high genetic heterogeneity. Using exome sequencing in 7 families with SRNS, we found a recurrent homozygous missense mutation (p.P209L) in the *TTC21B* gene encoding the retrograde intraflagellar transport protein IFT139, which was previously reported to cause isolated nephronophthisis (NPH). Interestingly, analysis of biopsies of SRNS patients revealed tubular basement membrane thickening and tubulointerstitial anomalies similar to NPH. Moreover, analysis of 3 unrelated patients carrying this homozygous mutation and initially diagnosed as NPH reveals that they also have proteinuria and glomerular lesions as in SRNS patients.

We demonstrated that IFT139 is expressed in podocytes and distal tubules in fetal and adult human kidneys. Developing podocytes in fetal kidney and undifferentiated podocytes *in vitro* have a cilium, whereas it is absent in mature and differentiated podocytes. IFT139 localizes at the base of cilia in undifferentiated podocytes, whereas it stains the extended microtubule network in non-ciliated differentiated cells. While the P209L mutant and wild-type IFT139 display similar subcellular distribution, over-expression of the P209L mutant in both podocytes and tubular cells leads to migration defects. Our results, showing for the first time a mutation of a gene encoding a ciliary protein in a glomerular disorder, point to a critical function of IFT139 in podocytes in addition to its well established role in tubular epithelial cells, likely via dysregulation of ciliary transport and microtubule network which are essential for cell migration, polarity and proper organization/maintenance of intercellular junctions, including the slit diaphragm.

C19.6

Characterization of the large patient cohort of the International Inflammatory Bowel Disease Genetics Consortium (IIBDGC)

I. Cleynen[1,2], *o. (IIBDGC)*[3];

[1]*Wellcome Trust Sanger Institute, Cambridge, United Kingdom,* [2]*KU Leuven, Leuven, Belgium,* [3]*IIBDGC, Cambridge, United Kingdom.*

Large-scale genetic studies performed by the IIBDGC have concentrated on Crohn's disease (CD) and ulcerative colitis (UC) overall. Their most recent study on ~75,000 individuals expanded the number of known IBD loci to 163. The enormous resource assembled by the IIBDGC provides an opportunity to evaluate clinically important sub-phenotypic variables and their

relation to genetic variation.
Clinical data on 14,569 CD and 10,867 UC have been collected (age at diagnosis, CD location and behaviour, UC extent, duration of follow-up···). QC analyses were done to identify non-random patterns of missing data and potential classification differences across centres. Genotype-phenotype analyses were performed using the Immunochip release 5 dataset, containing QC'd data on 157,020 variants.
The median age at diagnosis for CD was 23y (IQR 16-33), and 30y (21-43) for UC. 32% of CD patients had ileal (n=3252), 23% colonic (n=2376), and 45% ileocolonic (n=4619) disease. 25% of CD patients had stricturing (n=2574) and 31% penetrating (n=3188) disease. 13% of UC patients had proctitis (n=992), 38% left-sided (n=2941), and 49% extensive disease (n=3757). Genotype-phenotype analyses confirmed a genome-wide significant association for the CD-associated NOD2 locus and the MHC/HLA region with ileal versus colonic CD (rs2066843, p=2.99×10-38, OR=1.70[1.57-1.84] and rs6930777, p=1.83×10−19, OR=0.57[0.51-0.65] respectively). The MHC/HLA region was also associated with extensive UC (rs3115674, p=2.82×10−13, OR=1.47[1.32-1.62]). Interestingly the HLA signals for CD and UC overall are different from those for disease location/extent, warranting more detailed analysis.
These findings provide a robust platform for further analyses enhancing our understanding of the underlying pathogenesis of IBD sub-groups.

C20.1

RNA foci in C9FTD/ALS patients sequester RNA binding proteins and subsequently alter downstream splicing and expression of their RNA targets.

V. V. Belzil, *J. Chew, W. Lee, L. Petrucelli;*
Mayo Clinic, Jacksonville, FL, United States.

Background: Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are two devastating neurodegenerative diseases with substantial clinical and neuropathological overlap. This connection was confirmed by recent groundbreaking genetic studies identifying hexanucleotide (GGGGCC)$_n$ repeat expansions in the *C9ORF72* gene as the major cause of both ALS and FTLD-TDP, the most common pathological subtype of FTD. Transcripts containing the expanded GGGGCC repeat accumulate as nuclear RNA foci in the frontal cortex and spinal cord of *C9ORF72* mutation carriers, an RNA mechanism emerging as a common pathogenic process in many neurodegenerative diseases caused by non-coding repeat expansions. *Methods:* Considering the possibility of subsequent sequestration and altered activity of RNA-binding proteins by these foci and consequently altering the splicing and expression of their RNA targets, we attempted to determine using RNA FISH and commercially available antibodies whether RNA binding proteins already known to be sequestered by foci in patients affected with other neurodegenerative diseases also co-localize with C9ORF72 foci. After identifying two sequestered proteins, we sequenced the cDNA of C9FTD/ALS patients and conducted semi-quantitative as well as qRT-PCR for ten of their known RNA targets. Any variation in expression was confirmed by western blot. *Results:* Our findings confirm that RNA foci formation in C9FTD/ALS lead to the sequestration of two RNA binding proteins, and consequently to the aberrant splicing and expression of several targets. *Conclusions:* RNA foci formation in C9FTD/ALS leads to a loss of function of two sequestered RNA proteins, causing aberrant splicing and expression of genes having critical functions in neuronal survival.

Recent studies have shown that severe intellectual disability (ID) is mostly monogenic and highly heterogeneous. Small sibling families with ID have received little attention from the scientific community due to technical limitations to identify the underlying genetic defect. We studied 20 such families. Pathogenic mutations were identified in three genes. In *DDHD2*, compound heterozygous frameshift mutations where identified in a family with complex ID. Follow-up studies revealed recessive mutations in three additional families with a similar phenotype[a]. Further support that DDHD2 plays an essential role in the human CNS was obtained by a reduced number of active zones at synaptic terminals in Ddhd-knockdown Drosophila models. On the X-chromosome, mutations in *SLC9A6* and *SLC6A8*, both previously implicated in X-linked ID, were identified in two brotherpair families.
Six novel candidate genes for ID were identified. In one of these, a homozygous splice donor site mutation segregated in a brotherpair family. This mutation results in aberrant mRNA splicing and subsequent absent enzymatic protein activity. Rare recessive missense variations were identified in *SYNE1*, *ZNF582* and *MCM3AP*. In *PTPRT*, we identified a compound heterozygous deletion and missense variation. Lastly, a hemizygous missense variation in *BCORL1* on the X-chromosome was present in a brotherpair family.
In this study, we identified (potentially) pathogenic mutations in one novel, two known and six candidate ID genes in nine out of 20 (45%) families, thus demonstrating that recessive and X-linked mutations can readily be identified in small sibling families.

The recurrent 600kb-long 16p11.2 deletion and its reciprocal duplication impact carriers' cognition and behavior. These rearrangements are associated with mirror phenotypes such as obesity and underweight, macro- and microcephaly, as well as autism spectrum disorder and schizophrenia. Although these imbalances are among the most frequent causes of neurodevelopmental disorders, the triggered transcriptome alterations and their associations with the aforementioned phenotypes remained unexplored.
We generated transcriptome profiles of lymphoblastoid cell lines from 16p11.2 deletion and duplication carriers, as well as controls. The expression levels of the 29 genes mapping to the imbalanced interval correlate to their gene dosage. We observed a greater correlation of the expression levels of KCTD13, MVP and MAPK3, three genes shown to have an epistatic effect on zebrafish head size. To investigate the functional relationship between gene-expression levels and phenotypes, we transformed anthropometric measurements into Z-scores. We found that Z-scores computed for weight and BMI were significantly associated with MAPK3 and MVP expression after adjustment for copy-number status in a multivariate normal linear model for adults. We also show that transcription modules (subsets of genes that exhibit a coherent expression profile) involved in the regulation of gene expression, chromatin modification, control of apoptosis and cell division are perturbed in cells of 16p11.2 patients, further confirming the emerging association between "cancer-associated" genes/pathways and neurodevelopmental disorders. Of note, genes whose expression levels correlated with the number of copies of the 16p11.2 CNV were enriched for genes associated with intellectual disability and psychiatric disorders.

[1]*Radboud University Medical Centre, Nijmegen, Netherlands,* [2]*Aktogen Ltd., Department of Genetics, University of Cambridge, Cambridge, United Kingdom,* [3]*Institute of Biochemistry, Biological Research Center, Hungarian Academy of Sciences, Szeged, Hungary.*

Introduction: Family based whole exome sequencing (WES) is successful in the elucidation of causative *de novo* gene mutations in sporadic patients with intellectual disability (ID) not presenting with clinically recognizable syndromes. Establishing conclusive molecular diagnoses in patients with disruptive mutations in genes not previously associated with ID however, requires the identification of additional mutations in the same gene in similarly affected individuals.

Patients, Methods, Results: By WES we recently identified *de novo* loss-of-function mutations in *GATA zinc finger domain containing 2B (GATAD2B)* in two unrelated individuals. We identified an additional disruptive mutation in *GATAD2B* in a third individual by targeted Sanger sequencing in a selected cohort with phenotypic overlap. Detailed clinical characterization revealed a distinctive, highly similar phenotype comprising childhood hypotonia, severe ID, limited speech, abnormal shaped nose, sparse hair growth and strabismus, defining a novel clinically recognizable syndrome. Modelling of *GATAD2B* loss-of-function in *Drosophila* further confirmed its involvement in learning processes and synapse development.

Discussion: *GATAD2B* encodes a subunit of the MeCP1-Mi-2/ NuRD complex involved in transcriptional repression. It can be added to the growing list of ID genes implicated in chromatin remodelling. This study shows that exome sequencing is not only successful in the elucidation of responsible genes in established clinical syndromes, but has also the potential to identify and define novel clinically recognizable syndromes. Moreover, we faced the challenge to make conclusive decisions about the pathogenicity of *de novo* mutations in potentially novel ID genes, which ultimately requires the identification of disruptive mutations in similarly affected individuals.

Microdeletions of chromosomal region 2q23.1 that disrupt MBD5 contribute to a spectrum of neurodevelopmental phenotypes. To characterize the structural variation landscape of MBD5 disruptions and the associated human psychopathology, 22 individuals with genomic disruption of MBD5 (translocation, point mutation, and deletion) were identified through whole-genome sequencing or cytogenomic microarray at 11 molecular diagnostic centers. The genomic impact ranged from a single base pair to 5.4 Mb. Parents were available for 11 cases, all of which confirmed the rearrangement arose de novo. Phenotypes were largely indistinguishable between patients with full-segment 2q23.1 deletions and those with intragenic MBD5 rearrangements, including alterations confined entirely to the 5'UTR, confirming the critical impact of non-coding sequence at this locus. We identified heterogeneous, multi-system pathogenic effects of MBD5 disruption and characterized the associated spectrum of psychopathology, including the novel finding of anxiety and bipolar disorder in multiple patients. Importantly, one of the unique features of the oldest known patient was behavioral regression. Analyses also revealed phenotypes that distinguish MBD5 disruptions from seven well-established syndromes with significant diagnostic overlap. This study demonstrates that haploinsufficiency of MBD5 causes diverse phenotypes, yields insight into the spectrum of resulting neurodevelopmental and behavioral psychopathology, and provides clinical context for interpretation of MBD5 structural variations. Empirical evidence also indicates that disruption of non-coding MBD5 regulatory regions is sufficient for clinical manifestation, highlighting the limitations of exon-focused assessments. These results suggest an ongoing perturbation of neurological function throughout the lifespan, including risks for neurobehavioral regression.

Rare copy number variants (CNVs) at 15 different loci have been suggested as susceptibility factors for schizophrenia (SCZ). However, as some of these CNVs have only been observed in a single study, it is not clear whether they are true risk factors for the disorder. We set out to test the associations between these CNVs and SCZ, and to estimate their combined contribution in a large new sample of 6,882 cases and 6,316 controls genotyped with Illumina arrays. CNVs were called with PennCNV and verified with a Z-score algorithm.

We found higher rates in cases than in controls for 13 of the 15 previously implicated CNVs. Six were nominally significantly associated ($p<0.05$): deletions at 1q21.1, NRXN1, 15q11.2 and 22q11.2, and duplications at 16p11.2 and the Angelman/Prader-Willi Syndrome region. When combined with published data, 11 of the 15 loci showed highly significant evidence for association with SCZ ($p<4.1 \times 10\text{-}4$). Moreover, two CNVs surpassed genome-wide significance that had not done so previously: duplications at the Angelman/Prader-Willi locus and at 16p13.11. All eight Angelman/Prader-Willi duplications in cases were of maternal origin.

Our study strengthens the support for the majority of the previously implicated CNVs in SCZ and brings the evidence for two loci (duplications at the AS/PWS locus and at 16p13.11), into the genome-wide significant level. Overall, about 2.5% of SCZ patients and 0.9% of controls carry a large, detectable CNV at one of the previously implicated loci.

INTRODUCTION Connective tissue disorders are a common cause of vascular disorders, such as thoracic aortic aneurysm and dissection (TAAD). Cerebrovascular anomalies in connective tissue disorders are less frequently reported, although they can be associated with mutations in *TGFβR1*, *TGFβR2*, *SMAD3*, *ACTA2* and *COL3A1*, most frequently resulting in cerebral aneurysms, or mutations in *COL4A1* and *COL4A2*, resulting in hereditary porencephaly and cerebral hemorrhage. Recently, *ACTA2* mutations have been described in Moyamoya(like) disease and ischemic stroke. In addition, a specific phenotype has been ascribed to the R179H mutation, leading to a childhood presentation of disruption of smooth muscle cell dependent organs, brain developmental defects and abnormal cerebral vasculature.
METHODS We report on a patient presenting with pulmonary hypertension, patent DA, mydriasis, intestinal malrotation, bladder dysfunction and an abnormal, straightened course of the anterior cerebral arteries. Our patient shows previously not described abnormal lobulation of the frontal lobes and position of the gyrus cinguli and rostral dysplasia of the corpus callosum. She died at the age of 3 years during surgery due to vascular fragility and ductus arteriosus rupture.
RESULTS We identified a novel *de novo* c.535C>T in exon 6 leading to p.R179C amino acid substitution in *ACTA2.*
DISCUSSION Altogether these observations support a role of *ACTA2* in brain (vascular) development, especially related to the arginine at position 179. Although all previously reported patients with R179H substitution successfully underwent the same surgery at younger ages, the severe outcome of our patient warns against the devastating effects of the R179C substitution on vasculature.

Cherubism: a case report

T. H. ElBadry[1], *S. A. Temtamy*[1], *A. A. Abd El Azeem*[1], *M. I. Mehrez*[1], *M. A. El Kassaby*[2];
[1]*National Research Centre, Cairo, Egypt,* [2]*Faculty of Dentistry, Ain-Shams University, Cairo, Egypt.*

According to the WHO classification, cherubism belongs to a group of non neoplastic bone lesions that affect the jaws. Cherubism was first described in 1950 by Jones who described a condition which was characterized by marked fullness of the cheeks and jaws and a slight upturning of the eyes giving the children a cherubic appearance Cherubism is a hereditary disease with an autosomal dominant pattern of inheritance. Mangion et al. (1999) mapped the gene to 4p16.3. Mutations in the SH3BP2 gene was demonstrated (Ueki et al. 2001). Patients with cherubism should be carefully evaluated for Noonan syndrome. Clinically, in cherubism, the lesions usually start in early childhood, affect both jaws, and have a symmetric distribution. It begins to swell gradually until puberty. Although the condition is known to regress during the third decade of life, radiological changes persist until the fourth. Although the disease is rare and painless, the affected suffer the emotional trauma of disfigurement. cherubism interferes with normal jaw motion and speech. Currently, surgical removal of the fibrous tissue and bone is the treatment available. This treatment has no expected results, when introduced before puberty, results in an increase in bone growth .The use of calcitonin and bisphosphonate with these surgeries was found to enhance the outcome greatly and to prevent fierce recurrences. This report describes the clinical features of a 14-year-old girl with a severe case of cherubism affecting both jaws. We summarize the natural history of the disease over a period of 11 years.

Background:
A broad spectrum of 322 unique COL2A1 mutations is currently described in the corresponding LOVD database gene entry that we manage (https://grenada.lumc.nl/LOVD2/mendelian_genes/home.php?select_db=COL2A1). Heterozygous mutations in this gene cause a large panel of skeletal dysplasia classified as Type 2 collagen group and similar disorders.
Objective: To report on 54 unique mutations including 36 novel and to investigate possible phenotype-genotype correlation.
Methods: Molecular analysis of the COL2A1 gene in 112 patients with clinical diagnosis of skeletal dysplasia was performed by Sanger bidirectional sequencing.
Results:
We identified 54 unique pathogenic mutations including 35 (65%) missense, 5 (9%) nonsense, 7 (13%) frame-shifts and 7 (13%) splice-site distributed over the whole COL2A1 gene. Fourty-six of 54 (85%) were substitutions, with 23 of 46 (50%) resulting in glycine substitution within a Gly-X-Y repeat. Fifty-five (49.5%) of the 112 patients carried one COL2A1 mutation. Unexpectedly, 6 patients (3 Stickler, 1 Spondyloepiphyseal Dysplasia Congenita, SEDC, 1 Kniest and 1 Spondyloepimetaphyseal Dysplasia, Strudwick type) were compound heterozygous. Twelve (92%) of the 13 SEDC patients carried a glycine substitution, whereas the Stickler patients displayed a broader spectrum of mutations: 8 missenses, 4 nonsenses, 5 frame-shifts, and 4 splice-sites.
Conclusions:
This series of skeletal dysplasia, one of the largest reported so far, adds 36 (10%) novel mutations to those reported in LOVD and reveals first cases with dual mutations in these classically dominant syndromes. Moreover, we confirm that 51% of the Stickler patients carry COL2A1 mutation, and that this phenotype is associated with a larger mutational spectrum than SEDC.

P01.004

Craniofrontonasal Syndrome: A family with unusual inheritance pattern of an X-linked Dominant genetic disease.

B. Ozyilmaz[1], *A. Gezdirici*[2], *M. Özen*[2], *O. Kalenderer*[3];
[1]*Tepecik Training and Research Hospital, Department of Medical Genetics, İzmir, Turkey,* [2]*Cerrahpasa Medical Faculty, Department of Genetics and Teratology Research Center, İstanbul, Turkey,* [3]*Tepecik Training and Research Hospital, Department of Orthopedics, İzmir, Turkey.*

Craniofrontonasal syndrome (CFNS [MIM 304110]) is an X-linked dominant disorder of craniofacial and skeletal development. CFNS unexpectedly presents severe phenotype in heterozygous females and no or mild phenotype in hemizygous males. While heterozygous females show coronal craniosynostosis, craniofacial asymmetry, cleft palate, bifid nasal tip, Sprengel deformity, wiry hair and hypertelorism, males generally only show hypertelorism.
EFNB1 gene is located in Xq13.1 region and it is involved in random X-inactivation process in females. In heterozygous females, random X-inactivation process leads to mosaic distrubution of cells carrying mutant and wild type EFNB1 genes, thus the severity of heterozygous females is associated with patchy tissue pattern regarding the EFNB1 functional and non-functional cells. Here we report a Turkish family with CFNS. The parents were 5th degree relatives and they had 5 children. Two female sibs were similarly affected and 2 male sibs were healthy. The father and mother were not presenting any signs or symptoms regarding to CFNS. EFNB1 gene sequencing analysis revealed c.451G>A heterozygous mutation in 2 affected female sibs and unexpectedly c.451G>A hemizygous mutation in their clinically unaffected father. The identification of the clinically unaffected father as hemizygous for EFNB1 mutation, provides additional data for previously reported unusual genotype-phenotype pattern of the disease.

B. Ozyilmaz: None. **A. Gezdirici:** None. **M. Özen:** None. **O. Kalenderer:** None.

P01.005

Multiple craniosynostoses with unique digital anomalies: a new craniosynostosis syndrome?

V. M. Siu[1,2,3], *S. DeRibaupierre*[1,2], *D. Matic*[1,2], *K. Y. Tay*[1,2], *K. Norozi*[1,2,3], *N. D'Souza*[2];
[1]*University of Western Ontario, London, ON, Canada,* [2]*London Health Sciences Centre, London, ON, Canada,* [3]*Children's Health Research Institute, London, ON, Canada.*

Syndromic craniosynostosis syndromes are typically caused by single gene autosomal dominant disorders or chromosomal duplications or deletions. We report a 15 month old girl with multiple congenital anomalies. She was born with bilateral coronal synostosis and abnormal occipital bone with premature fusion of the supraoccipital and interparietal portions, resulting in turribrachycephaly, hypertelorism, and downslanting palpebral fissures. Transverse and sigmoid sinuses are congenitally absent, and a large single vein from the superior sagittal sinus drains into large scalp veins through the posterior fontanelle. At 3 months, she developed severe intracranial hypertension requiring a posterior craniectomy and ventriculoperitoneal shunt. Surgical correction of the skull deformities has been challenging. She had redundant nuchal skin, a ventricular septal defect (spontaneously closed), and a persistently patent ductus arteriosus. Her symmetric hand anomalies involve hypoplasia of the proximal phalanges of the thumb and index fingers, and hypoplasia of the middle phalanges of the 3rdand 5th digits, resulting in marked brachydactyly and ulnar deviation of the index fingers, and 5th finger clinodactyly. The 4th digits are spared. Radii appear normal. Family history is negative for any of these features. Array CGH using a 180k oligonucleotide array, as well as full sequencing of FGFR2 and FGFR3, targeted mutation analysis of FGFR1, and gene dosage studies of TWIST1 have not identified any alteration to account for these features. We propose that this disorder represents a previously undescribed craniosynostosis syndrome with multiple congenital anomalies. Next generation sequencing may potentially aid in the identification of the causative gene.

P01.006

Expression of the Bardet-Biedl Syndrome gene 9 (BBS9) in calvarial suture of nonsyndromic craniosynostosis: pathophysiology of primary cilium in suture morphogenesis.

C. Bernardini[1], *M. Barba*[1], *G. Tamburrini*[2], *S. A. Boyadjiev Boyd*[3], *C. Di Rocco*[2], *F. Michetti*[1], ***W. Lattanzi***[1];
[1]*Inst. Anatomy and Cell Biology, Università Cattolica S. Cuore, Rome, Italy,* [2]*Dept. Neurosurgery - Pediatri Neurosurgery Unit- Università Cattolica S. Cuore, Rome, Italy,* [3]*Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA, United States.*

Nonsyndromic craniosynostosis (NCS) is a relatively common craniofacial malformation, with a strong genetic background. A recent GWAS found a significant association for sagittal NCS (sNCS) within the BBS9 gene locus (*Justice et al, Nat Genet 2012*). BBS9 is a component of the BBBSome involved in the primary cilium-related signalling. BBS9 knockdown leads to cilia defect in the zebrafish, displaying severe developmental aberrations (*Veleri et al, PlosOne 2012*). Interestingly, genes causing at least two craniosynostosis syndromes (Carpenter and Sensenbrenner syndrome) are involved in the cilia formation and function (*Huber and Cormier-Daire, Am J Med Genet C Semin Med Genet.2012*). This study was aimed at clarifying the role of BBS9 and related cilium-associated genes in suture ossification. We have performed an in-depth in silico analysis of our previous microarray data and identified a relevant number of ciliome-associated genes differentially expressed in fused-versus-patent sutures of NCS patients. BBS9 was among the most significantly up-regulated genes in the list; these data were confirmed in tissues and cells from an independent set of NCS patients. Confocal microscopy showed that fused suture-derived cells has a decreased tendency to form primary cilia. Moreover we have analyzed the expression of BBS9 and related cilium-associated genes in the suture mesenchyme of the rat skull. The expression of BBS9 increased progressively over time. Overall, these data seemed to confirm an active role of BBS9 in osteogenesis and may suggest that BBS9 sequence variants associated to a dysregulation of BBS9 expression could lead to premature suture ossification in NCS.

P01.007

FGFR2 mutations in syndromic craniosynostosis patients

A. Durmaz[1], *H. Onay*[1], *T. Atik*[2], *E. Karaca*[1], *F. Hazan*[3], *A. Kiraz*[4], *G. Yesil*[5], *O. Cogulu*[2], *F. Ozkinay*[1];
[1]*Ege University Medical Faculty, Department of Medical Genetics, Izmir, Turkey,* [2]*Ege University Medical Faculty, Department of Pediatrics, Izmir, Turkey,* [3]*Dr. Behçet Uz Children's Hospital, Department of Medical Genetics, Izmir, Turkey,* [4]*Mersin Hospital of Pediatrics, Obstetrics and Gynocology, Department of Medical Genetics, Mersin, Turkey,* [5]*Bezmialem University, Medical Faculty, Department of Genetics, Istanbul, Turkey.*

Craniosynostosis which is defined as the premature fusion of one or more sutures of the skull is caused by mutations in FGFR1, FGFR2, or FGFR3. Among all craniosynostosis, syndromic craniosynostosis account for 15% of the cases. The most common forms of syndromic craniosynostosis are Crouzon, Apert, Pfeiffer and Muncke syndrome that are mostly caused by mutations in FGFR2 gene in which more than 60 mutations have been identified up to date. In this study we screened for FGR2 mutations in 8 patients having Crouzon, Apert and Pfieffer syndromes. We found heterozygous FGFR2 mutations (p.P253R in 2 patients and p.S252W in one patient) in 3 Apert syndrome patients which were also reported to be the most common mutations in Apert syndrome. In 3 Crouzon syndrome patients heterozygous p.W290R, p.S351C and p.S252P mutations were detected. Heterozygous p.W290C mutation was found in one patient diagnosed clinically as Pfeiffer syndrome. One novel heterozygous mutation p.F334S has been detected in a patient with isolated nonsyndromic craniosynostosis. SIFT and PolyPhen analysis demonstrated that this aminoacid change may be tolerated, but functional analysis is needed. Revealing the phenotype-genotype correlation of particular syndromic forms of craniosynostosis leads to accurate diagnosis, efficient management, and long-term prognosis of the patients.

Rapid translation of research findings into clinical service for two new craniofacial genes identified in Oxford.

H. Lord[1], *T. Lester*[1], *S. R. F. Twigg*[2], *V. P. Sharma*[2], *A. L. Fenwick*[2], *S. J. McGowan*[3], *J. M. Phipps*[2], *D. Johnson*[4], *S. A. Wall*[4], *L. Wilson*[5], *F. Stewart*[6], *J. Morton*[7], *P. Noons*[8], *E. Sweeney*[9], *A. O. M. Wilkie*[2], *A. Seller*[1];
[1]*Oxford Regional Genetics Laboratories, Churchill Hospital, Oxford, United Kingdom,* [2]*Clinical Genetics Group, Wetherall Institute of Molecular Medicine, University of Oxford and Craniofacial Unit, John Radcliffe Hospital, Oxford, United Kingdom,* [3]*Computational Biology Research Group, Wetherall Institute of Molecular Medicine, University of Oxford and Craniofacial Unit, John Radcliffe Hospital, Oxford, United Kingdom,* [4]*Craniofacial Unit, John Radcliffe Hospital, Oxford, United Kingdom,* [5]*Clinical Genetics, Level 4, York House, Great Ormond Street NHS, London, United Kingdom,* [6]*Northern Ireland Regional Genetics Service, Belfast City Hospital, Lisburn Road, Belfast, United Kingdom,* [7]*Clinical Genetics, Birmingham Women's Hospital, Metchley Park Road, Edgbaston, Birmingham, United Kingdom,* [8]*Birmingham Children's Hospital, Steelhouse Lane, Birmingham, United Kingdom,* [9]*Clinical Genetics Department, Alder Hey Children's NHS Trust, Eaton Road, Liverpool, United Kingdom.*

Craniosynostosis (premature fusion of at least one cranial suture) results in skull and facial deformity, and is the second most common craniofacial malformation. Currently, single gene mutations/chromosomal abnormalities can only be identified in about one-fifth of cases, with mutations in the FGFR2, TWIST1, FGFR3, and EFNB1 genes accounting for the majority (~16%). Identifying the genetic cause in infants is important for genetic counselling, risk assessment, surgical management and outcome.

Close partnership between the diagnostic Oxford Regional Genetics Laboratory and Professor Wilkie's research group in Oxford has enabled two new craniofacial genes; ERF and TCF12, to be rapidly translated into the diagnostic service. Mutations in these two genes have been shown to account for a further ~2% of cases.

To date we have screened seventeen patients with multi-suture synostosis in whom no mutation was identified in previous screens. An ERF mutation was detected in one patient with pansynostosis.

Of fifteen patients referred with uni- or bi-coronal synostosis, in whom no mutation was identified in previous screens; two patients were shown to carry a mutation in TCF12.

Confirmation of other mutations in ERF and TCF12 identified in the research setting is currently in progress, and we have also undertaken cascade screening in two of these families. This is important as variable penetrance has been observed.

Incorporation of these new genes into our diagnostic service has identified the genetic cause in three new cases in our cohort, which will enable cascade screening and accurate prognostic advice to be given.

Crouzon Syndrome and bent bone dysplasia associated to mutations at the same TYR-381 residue in FGFR2 gene

C. Collet[1], *J. Alessandri*[2], *E. Arnaud*[3], *V. Cormier-Daire*[4], *F. Di Rocco*[3];
[1]*Service de Biochimie et Biologie Moléculaire, Hôpital Lariboisière, Paris, France,* [2]*Service de Réanimation Pédiatrique, Hôpital Felix Guyon, Saint-Denis de la Réunion, France,* [3]*Unité de Chirurgie Craniofaciale, Service de Neurochirurgie, Centre de Référence National Dysostoses Crâniofaciales, hôpital Necker, Paris, France,* [4]*Génétique Clinique, Centre de Référence des Maladies Osseuses Constitutionnelles, Hôpital Necker, Paris, France.*

Crouzon syndrome has an high penetrance and an extreme clinical variability. The majority of the mutations responsible for his syndrome are located in the exon 8 (IIIa) and 10 (IIIc) of the fibr oblast growth factor receptor 2 gene (FGFR2) corresponding to an immunoglobulin domain. We report here a familial Crouzon syndrome associated to a new p.Tyr381Asn mutation in exon 11 of FGFR2 gene. The proband was suspected of this syndrome at the age of 3 years. At that time he presented with adolichocephaly with bilateral moderate exophtalmia, parrot-beaked nose and frontal bossing. A skull CT examination was performed at age 5 confirming the closure of the sagittal suture associated a facial retrusion and inverted bite. His father and his sister displayed a milder phenotype. The Crouzon syndrome was confirmed after detection of novel heterozygous p.Tyr381Asn(c.1141T>C) mutation in FGFR2 gene located in the transmembrane domain for the 3 affected members of the family, segregating with the craniosynostosis phenotype. This mutation was located at the same position (p.Tyr381Asp(c.1141T>G)) that the recently described perinatal lethal bent bone dysplasia which is characterized by co ronal craniosynostosis associated with hypoplastic clavicle, bent long bones in the lower extremities, hypoplastic pubis and abnormal phalanges. Ours cases did not show any appendicular bony abnormality on X-rays. This observation highlights the need of further researches to explain such major clinical difference between those two syndromes associated with a FGFR2 mutation affecting the same Tyr-381 residue.

P01.010

1150 T>C change in exon 10 of the *FGFR3* is preferentially associated with pathogenic mutations

T. Y. Kanazawa*, L. C. Bonadia, C. A. Moreno, D. P. Cavalcanti;*
State University of Campinas, Campinas, Brazil.

Few pathogenic mutations in *FGFR3* are known to be associated with the achondroplasia phenotypic spectrum, leading to a good genotype-phenotype correlation. Uncommonly, however, phenotype variations have been observed. The speculation about a possible modulating effect of the 1150 T>C transition in the *FGFR3*, and the identification of a newborn with a severe form of hypochondroplasia with positive mutation (1620 C>A) and also presenting the 1150 T>C substitution in the exon 10 prompted us to better investigate the role of this polymorphism. We evaluated the frequency of the 1150 T>C polymorphism in the *FGFR3* in both - a cohort of patients of the FGFR3 phenotypic spectrum with known mutations, and in normal controls of the general population. Hitherto, using direct sequencing of the exon 10 of the *FGFR3*, we have studied 39 patients and 265 normal controls. We have found the 1150 T>C polymorphism in two patients (2 alleles in 78 chromosomes or 2.6% of the C allele). One patient had a typical achondroplasia (1138 G>A) and the second one was a hypochondroplastic patient (1620 C>A) with a severe phenotype. Among the 265 studied controls, the 1150 T>C polymorphism was found in only three individuals (3 alleles in 530 or 0.6% of the C allele). In conclusion, the 1150 T>C polymorphism was found nearly five times more frequent in patients of the FGFR3 family than in normal controls, suggesting a possible role in pathogenic mutations of the *FGFR3*.

P01.011

A new insight into structural and functional impact of FGFR3 mutations at the same position in three FGFR3-related chondrodysplasia.

D. Komla Ebri[1], *C. Benoist Lasselin*[1], *N. Kaci*[1], *P. Busca*[2], *G. Prestat*[2], *A. Munnich*[1], *F. Barbault*[3], *L. Legeai-Mallet*[1];
[1]*INSERM U781, Paris, France,* [2]*UMR CNRS 8601, Paris, France,* [3]*ITODYS - Université Paris Diderot, Paris, France.*

Three missense mutations in the tyrosine kinase domain of fibroblast growth factor receptor 3 (FGFR3) affecting a lysine residue at position 650 lead to dwarfism with a spectrum of severity, hypochondroplasia (p. Lys650Asn), severe achondroplasia with developmental delay and acanthosis nigricans (p. Lys650Met), and thanatophoric dysplasia (p. Lys650Glu). Fgfr3 mutations induce a constitutive activation of the receptor characterized by a sustained phosphorylation. To understand the severity of the clinical phenotype, we developed computational and biological studies. Computational studies were conducted to get an atomic description of the p. Lys650Met, p. Lys650Glu and p. Lys650Asn built using a validated structural model of the FGFR3 kinase domain. Structural analyses indicate that a salt bridge between R655 and E686 is the cornerstone of the Tyr647 solvent exposition. This salt bridge is, significantly, disturbed with p. Lys650Glu mutation and is destroyed with p. Lys650Met and p. Lys650Asn mutants. There is a qualitative correlation with the severity of the clinical phenotype. We evaluated also the impact of the FGFR3 mutants on signaling pathways. Transient transfections of DNA mutants in human chondrocytes show both a gradient of phosphorylation levels and an increased proliferation correlated with the severity of the disease. In addition, a higher activation of the signalling pathways (ERK1/2, AKT, STAT, b-catenin) was also observed.
In conclusion, the three lysine 650 substitutions alter differently the conformation of the kinase domain thus leading to various activations of signalling pathways. Different mechanisms seem to be responsible for mild and lethal dwarfism.

Osteoporosis has its origins in childhood, where bone mineral accretion during development is a critical determinant of future bone health. We elected to leverage data from an ongoing GWAS of pediatric bone accretion to investigate the association of previously reported adult BMD loci with pediatric BMD of the spine using a linear regression based meta-analysis of three ethnicities. Our cohort is derived from the multi-center NICHD Bone Mineral Density in Childhood (BMDC) Study, which was initiated in 2001 to establish national reference standards for BMD and bone accrual for children ages 6 years and older. In order to maximize the statistical power in our cohort, we carried out a meta-analysis leveraging the three main ethnicities in the collection. This led to 753 Caucasian, 308 African American and 205 Hispanic samples being included in the analysis. All samples were genotyped on the Illumina OMNI-Express-Exome BeadChip platform, enabling us to query 59 of the 64 adult BMD. A linear regression in plink was used to test for association with pediatric spine BMD followed by a meta-analysis. No association was found when the three groups were analyzed together, but when investigating each ethnicity individually, we found that SNP rs940347 at the STARD3NL locus yielded a P-value of 1.74x10-4 in the Caucasian cohort and survived Bonferroni correction; indeed, this is the same ethnicity where the original adult discovery was made. In summary, we conclude that there is evidence that the STARD3NL locus contributes to adult spine BMD by exer-

ting its effect early in life.

The gray platelet syndrome (GPS) is a rare inherited bleeding disorder characterized by thrombocytopenia, increased volume of platelets and defects of α-granules formation which gives a characteristic gray appearance to platelets.
After the recent identification of mutations in NBEAL2 gene as the genetic defect responsible for GPS, we hypothesized that this gene was responsible for low platelet count and α-granule deficiency in 11 unrelated probands with inherited thrombocytopenia and α-granules defects.
DNA sequencing of NBEAL2 led to identification of 9 novel alteration of the gene including 2 missense, 3 nonsense, 2 frameshift mutations, as well as 2 nucleotide substitutions that altered the splicing mechanisms, in 4 families. In addiction, evaluation of platelet phenotype revealed that all patients with NBEAL2 biallelic mutation showed thrombocytopenia, large platelets and severe reduction of α-granules. Of note, although they were not thrombocytopenic, also individuals carrying only one mutated allele had platelet macrocytosis and significant reduction of the α-granules in contrast with an autosomal recessive transmission. In the remaining 7 probands, we did not identify any NBEAL2 alterations, suggesting that other genetic defects are responsible for their platelet phenotype.
Our data extend the spectrum of mutations responsible for GPS and demonstrate that macrothrombocytopenia with α-granule deficiency is a genetic heterogeneous trait.

Osteoporosis is characterized by very low bone mineral density (BMD). The high bone mass (HBM) phenotype is a non-pathogenic condition characterized by BMD values at the other extreme of the spectrum. The aims of the study were to establish the prevalence of HBM in a cohort of Spanish postmenopausal women (BARCOS); to determine the contribution of LRP5 and DKK1 mutations to this phenotype; to test the hypothesis of an inverse correlation between the number of common variant risk alleles and HBM; and to characterize the expression of 88 osteoblast-specific and Wnt pathway genes in primary osteoblasts from two HBM cases.
A 0.6% of individuals (10/1600) displayed bone mineral density Z-scores in the HBM range [sum (lumbar spine + femoral neck) Z-score >4]. No mutations in relevant exons of LRP5 were found and one woman had a rare missense change in DKK1 (p.Y74F). Fifty-five BMD SNPs from Estrada et al [NatGenet 44:491-501,2012] were genotyped in the HBM cases to obtain risk-scores for each individual. Z-scores were found to be negatively correlated with these risk-scores, with a single exception, which may be explained by a rare penetrant genetic variant. The expression analysis in primary osteoblasts from two HBM cases and five controls, showed that IL6R, DLX3, TWIST1 and PPARG were negatively related to Z-score. One HBM case presented with high levels of RUNX2 while the other displayed very low SOX6. In conclusion, we provide evidences of heterogeneity and of additive effects of several genes for the HBM phenotype.

Epiphyseal-vertebral-ear (EVE) dysplasia is an extremely rare disorder with distinctive dysmorphic features and ossification defects. A single family has been reported, with two affected sisters born to healthy, consanguineous parents. Key features were midface hypoplasia, depressed nasal bridge, anteverted nares, symmetrical dysplasia of the helices, epiphyseal dysplasia, mid-coronal clefting of vertebral bodies, odontoid hypoplasia, elbow dislocation and intrauterine growth restriction with post-natal catch-up growth. Similar craniofacial and skeletal features have been noted in cerebral, ocular, dental, auricular, skeletal anomalies (CODAS) syndrome. The genetic causes of EVE and CODAS syndromes have not been reported.We performed exome sequencing of the two affected EVE dysplasia patients, and after filtering for published and in-house SNPs and selecting for deleterious variants, the only homozygous variant shared between both sisters was the missense mutation p.Thr362Ile in heat shock 70kDa protein 9 (HSPA9). The catalytic activity of HSPA9 is encoded by the ATPase domain, a structure conserved in chaperones from vertebrates to bacteria. Thr362 is absolutely conserved in known orthologues of HSPA9 and falls within the ATPase domain. Structural modelling of the mutation Thr362Ile indicates disruption of hydrogen bonding, predicted to lead to protein instability. Published transcriptomic data indicates that *HSPA9* is highly expressed in human fetal cartilage, and we have explored this expression pattern in greater detail by in situ hybridisation.This work identifies *HSPA9* as a novel regulator of craniofacial and skeletal development, with its mutation causing EVE dysplasia. CODAS syndrome may be caused by mutations in a related gene or pathway.

The genetic study of intracranial aneurysm in the Japanese population

S. Low[1], *A. Takahashi*[1], *M. Kubo*[2], *Y. Nakamura*[3];
[1]*Laboratory for Statistical Analysis, Center for Genomic Medicine, RIKEN, Tokyo, Japan,* [2]*Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Yokohama, Japan,* [3]*Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.*

Intracranial aneurysms (IA) are balloon like dilation of arterial walls in the brain; rupture of IA leads to aneurysmal subarachnoid hemorrhage (aSAH), which is the most serious subtype of stroke. Genetic factors have been known to play an important role in the development of IA. Here, we conducted a genome-wide association study (GWAS) to identify common genetic variants that are associated with IA by using 1383 aSAH subjects and 5484 controls from the Japanese population. The variants that showed suggestive association in the GWAS were validated in an independent set of 1048 IA cases and 7212 controls. We identified, rs6842241, near *EDNRA* at chromosome 4q31.22 (combined P-value = 9.58×10^{-9}; odds ratio = 1.25), to be significantly associated with IA. Owing to the functional importance of *EDNRA* to IA, we performed functional analysis of the associated variants on *EDNRA* and identified rs6841581 as a functional variant that might affect the expression of EDNRA and subsequently result in the IA susceptibility. To further understand the etiology of the disease, we performed pathway analysis utilizing the GWAS dataset and identified Notch signaling pathway to be significantly associated with IA ($P_{GSEA}=3.0 \times 10^{-6}$). In addition, we also participated in a collaborative study that performed meta-analysis, which successfully identified six genetic loci, 8q12.1, 9p21.3, 10q24.32, 13q13.1, 18q11.2 and 4q31.22, as IA common susceptible loci of the European and

Japanese population. Our findings have reveal a better understanding of the contribution of genetic factors to IA.

Gnathodiaphyseal dysplasia (GDD) is an autosomal dominant syndrome characterized by frequent bone fractures at a young age, bowing of tubular bones and cemento-osseus lesions of the jawbones. To date, two mutations on the same cysteine residue at position 356 of Anoctamin 5 (ANO5) have been described in GDD families. Sequencing the entire ANO5 coding and untranslated regions in 21 individuals (7 affected, 14 not affected) of a large Italian GDD family, we found a novel missense mutation causing the p.Thr513Ile substitution. The mutation perfectly segregates in the family and has never been described in any database as a polymorphism. Clinical features of the patients are completely superimposable to those of previously described families . Thus this is the third mutation described to be causative for GDD. ANO5 belongs to the anoctamin protein family that includes calcium-activated chloride channels. However, our experiments show that ANO5 may not function as calcium-activated chloride channel. Mutations in ANO5 have also been found in many cases of rare forms of muscular dystrophy (MMD3 and LGMD2L). The mutations described until now are spread throughout the gene, with no apparent trend in their position with regard to specific motifs, transmembrane domains or cytoplasmic versus extracellular regions of the protein. This heterogeneity and the still-unknown function of ANO5 make it difficult to unravel the molecular pathophysiology of GDD. The findings of this third mutation may help in this unraveling process and in the understanding of the anoctamins' function and role in these different diseases.

A Clinical and Molecular Genetic Study of 6 Arab families with Microcephalic Osteodysplastic Primordial Dwarfism type I

L. K. Effat;

Division of Human Genetics and Genome Research, giza, Egypt.

Backgroud: Microcephalic osteodysplastic primordial dwarfism type I (MOPD I) is a rare recessive disorder characterized by severe microcephaly, intrauterine growth retardation, developmental brain malformations, skeletal changes and early lethality. It is caused by mutations in the RNU4ATAC gene encoding U4atac, a small nuclear RNA that is a crucial component of the minor spliceosome. Objective: To determine the spectrum of clinical and neuroradiologic features in MOPD I patients due to RNU4ATAC gene mutations. Methods: RNU4ATAC was sequenced in 10 patients from 6 unrelated Arab families with MOPD I. In addition, we evaluated the clinical phenotype, cognition, behavior and brain MRI.
Results: All patients were homozygous or compound heterozygous of RNU4-ATAC mutations. The probands harbored 4 different mutations (g.55G>A, g.51G>A, g.66G>C and g.124G>A) of which 2 were novel. The severity of brain and skeletal anomalies, degree of motor and speech delay, and survival varied considerably among patients even with the same mutation. Mild motor delay was noted in 3/10 patients. Typical skeletal changes were found in all patients but metopic suture synostosis were additional finding in 5 patients. All patients showed hypogenesis of corpus callosum but 2 patients had pachygyria and interhemispheric cyst in addition. Interestingly, 4 sibs from showed oculocutaneous albinism. One patient showed long survival (more than 5 years) Conclusions: We provide a detailed description of features associated with RNU4ATAC mutations. Our results expand the phenotypic and mutational spectrum of this malformation syndrome and further investigations of the prevalence of RNU4ATAC mutations in correlation with clinical phenotype are recommended.

Multicentric carpo-tarsal osteolysis (MCTO) with or without nephropathy is a rare osteolysis disorder with autosomal dominant inheritance beginning in early childhood and involving mainly carpal and tarsal bones. In the majority of cases, renal disease appears later in life and evolves quickly to end stage renal disease. Recently, mutations in the amino-terminal transcriptional activation domain of the MAFB gene (v-maf musculoaponeurotic fibrosarcoma oncogene ortholog B) have been identified in MCTO patients by exome sequencing. MAFB, known as a regulator of various developmental processes, is essential for osteoclastogenesis and podocyte differentiation and renal tubule survival. We collected the data of eight patients with MCTO issued from six different families to review the clinical features and perform the molecular analysis of *MAFB*. Among the 8 cases, renal disease was present in the six older. We identified five missense mutations in all screened cases confirming the genetic homogeneity of MCTO. Three among the five mutations were novel clustered within the hot spot mutation region of the gene. Disease variability and associated features were observed , concerning especially the extension and consequences of osteolysis and age of onset of renal manifestations. Since the intensity of rheumatologic and nephrologic symptoms varied even within the same family, we conclude that MCTO is a genetically homogeneous but clinically variable condition; the molecular screening of *MAFB* will allow early diagnosis especially in isolated cases.

Nail-Patella Syndrome: evidence for genetic heterogeneity

F. M. Petit[1,2], *F. Escande*[1], *A. Jourdain*[1], *N. Porchet*[1,2], *M. Holder-Espinasse*[1,2,3], *S. Manouvrier-Hanu*[1,2];

[1]*CHRU de Lille, LILLE, France,* [2]*Université Lille Nord de France, Lille, France,* [3]*Guy's Hospital, London, United Kingdom.*

Nail patella syndrome (NPS) is a hereditary osteo-onychodysplasia with autosomal dominant inheritance. Prevalence is estimated at 1/50 000. This affection comprises characteristic skeletal anomalies (nail dysplasia, hypoplastic or absent patella, iliac exostoses···) frequently associated with ocular or renal involvement. NPS results from mutations in the *LMX1B* gene, localized in 9q34 and spanning approximately 95 kb. This gene encodes a transcription factor belonging to the LIM homeodomain protein family. This protein plays a crucial role in the dorso-ventral polarisation of the limbs. Mutations responsible for haploinsuffficiency of *LMX1B* are identified in 85-90% of patients.
In about 10-15% of patients, no mutation is identified in *LMX1B*. To our knowledge, the hypothesis of a genetic heterogeneity has never been studied in this disease. We study 5 families affected with typical NPS for whom routine screening has not identified a mutation in *LMX1B* (exons and flanking introns sequencing, MLPA). We performed NGS for the whole *LMX1B* gene in 4 families, revealing no mutation in coding or non-coding sequence. In one family, results provide clues for non-linkage at 9q34, confirming the likelihood of a genetic heterogeneity.

F.M. Petit: None. **F. Escande:** None. **A. Jourdain:** None. **N. Porchet:** None. **M. Holder-Espinasse:** None. **S. Manouvrier-Hanu:** None.

P01.022

Genetic variants in SKI, FGFR1, WNT3, IRF6 and BMP4 genes are associated with risk for non-syndromic CL/CLP and/or CP in Latvian population

I. Kempa[1,2], *L. Piekuse*[1], *I. Akota*[3], *B. Barkane*[3], *A. Krumina*[4], *J. Stavusis*[4], *J. Klovins*[4], *B. Lace*[4];
[1]*Scientific Laboratory of Molecular Genetics, Riga Stradins University, Riga, Latvia,* [2]*Department of Biology and Microbiology, Riga Stradins University, Riga, Latvia,* [3]*Department of Oral and Maxillofacial Surgery, Institute of Stomatology, Riga Stradins University, Riga, Latvia,* [4]*Latvian Biomedical Research and Study Centre, Riga, Latvia.*

The identification of susceptibility genes for non-syndromic cleft lip with or without cleft palate and isolated cleft palate (CL/CLP/CP) has been the subject of extensive research. To localize candidate genes and loci of non-syndromic clefts, several genome-wide linkage screens, association studies and fine mapping have been published. However, only the *IRF6* gene has shown a convincing degree of consistency across studies and was considered to be responsible for less than 20% of non-syndromic CL/CLP and/or CP.
The aim of the present study was the identification of candidate genes involved in the etiology of non-syndromic CL/CLP and CP in Latvian population. Selection of the candidate genes were based on recent publications regarding confirmed linkage and association studies with non-syndromic CL/CLP or CP. Genotyping of 672 SNPs in 45 genes were done using APEX-2 technology, MALDI-TOFF technology and TaqMan assays. For case-control study 178 non-syndromic CL/CLP/CP patients (135 CL/CLP patients and 43 CP patients) and 483 unaffected individuals as controls were analyzed, in addition TDT was carried out in 122 trios.
Our results showed very strong association between *FGFR1*, *WNT3*, *SKI*, *BMP4* and *IRF6* genes and non-syndromic CL/CLP and CP, and possible interaction between 19q13 locus and non-syndromic CL/CLP. Genetic variants in *SKI*, *FGFR1, WNT3* and *IRF6* genes may contribute susceptibility to both non-syndromic CL/CLP and CP, whereas *BMP4* gene could have protective effect in the susceptibility for non-syndromic CL/CLP in Latvian population.
Obtained results continue to support the involvement of these genes in the development of non-syndromic CL/CLP/CP in Caucasians.

Genome-wide analysis of parent-of-origin effects in non-syndromic orofacial clefts

K. U. Ludwig[1,2], *P. Garg*[3], *A. C. Boehmer*[1,2], *M. Rubini*[4], *R. Steegers-Theunissen*[5], *P. A. Mossey*[6], *M. M. Noethen*[1,2], *E. Mangold*[2], *A. J. Sharp*[3];
[1]*Department of Genomics, Life&Brain Center, Bonn, Germany,* [2]*Institute of Human Genetics, University of Bonn, Bonn, Germany,* [3]*Mount Sinai School of Medicine, Department of Genetics and Genomic Sciences, New York, NY, United States,* [4]*University of Ferrara, Department of Experimental and Diagnostic Medicine, Ferrara, Italy,* [5]*Erasmus Medical Center, Department of Obstetrics and Gynaecology, and Clinical Genetics, Rotterdam, Netherlands,* [6]*University of Dundee, Orthodontic Unit, Dental Hospital & School, Dundee, United Kingdom.*

Non-syndromic orofacial clefts (NSOFC), one of the most common congenital malformations, have a genetically complex background. Although recent GWAS detected a number of NSOFC susceptibility loci, these conventional association studies have the inherent presumption that the effect of a variant is independent of parental origin. They are thus underpowered to detect possible parent-of-origin (PofO) effects, a phenomenon where the effect of an allele on phenotype depends on whether it was transmitted by the mother or the father. In this study we hypothesized that PofO effects play a role in NSOFC etiology.
We applied a number of statistical tests on published genome-wide SNP data from ~2500 trios with NSOFC, mainly of European and Asian ethnicity. These tests included a modification of the family-based Transmission Disequilibrium Test, biased ratios of maternal versus paternal transmissions, and biased frequencies of reciprocal classes of heterozygotes in the offspring. Sixty-four candidate SNPs were followed-up in a replication cohort of ~1200 NSOFC trios of European origin.
In the combined analysis, we did not identify any SNPs that achieved genome-wide significance. However, we observed an overall excess of maternal versus paternal signals (P=0.013) and identified several loci that showed nominally significant effects in the same direction in both discovery and replication cohorts, suggesting variants with potential PofO effects which escaped the genome-wide threshold due to the lack of power. Those latter include a possible maternal effect associated with rs12543318 at 8q21.3, a locus also identified in a recent meta-analysis of non-syndromic cleft lip with/without cleft palate (Pmat=1.5x10-7, Ppat=0.17).

Genome-wide association study reveals new candidate loci for knee osteoarthritis

A. Näkki[1], *M. Heliövaara*[2], *P. Leino-Arjas*[3], *U. M. Kujala*[4,5], *J. Saarela*[1];
[1]*Institute for Molecular Medicine Finland FIMM, Helsinki, Finland,* [2]*National Institute for Health and Welfare, Helsinki, Finland,* [3]*Finnish Institute of Occupational Health, Helsinki, Finland,* [4]*University of Jyväskylä, Jyväskylä, Finland,* [5]*ORTON Orthopedic Hospital, Helsinki, Finland.*

Objective. Osteoarthritis is a complex disease common in the elderly. Our aim was to study single-nucleotide polymorphisms (SNPs) in genome-wide association study (GWAS) of knee OA.
Methods. The study subjects were part of Finnish Health2000 study sample (Genmets) consisting of 2118 individuals genotyped using Illumina HumanHap 610k. Presence of osteoarthritis in the knee joints were evaluated by a clinician based on physical status, symptoms, and medical history. Individuals suffering from rheumatoid arthritis or below the age of 50 were excluded. Seventy-five individuals had OA in at least one knee and 895 were healthy controls without knee or hip OA based on the clinical evaluation. Association was monitored using the Plink program, age, sex and body mass index as covariates.
Results. In the knee OA GWAS analysis the most significant results were for SNPs in or next to MARK1 gene on chromosome 1q41 (OR=2.44, 95%CI 1.68-3.54, p=2.67x10-6), MYO10 gene on chromosome 5p15.1 (OR=2.61, 95%CI 1.71-4.00, p=9.19x10-6), and on chromosome 13q21.1 (OR=2.29, 95%CI 1.59-3.28, p=7.12x10-6).
Conclusion. Variants in/near MARK1 and MYO10 showed suggestive evidence for association with knee OA. MARK1 plays a role in cell polarity and microtubule dynamics. MYO10 has a role in integration of F-actin and microtubule cytoskeletons during meiosis. Results did not reach genome-wide significance, but a follow-up study in an independent study set is ongoing: The three SNPs are being genotyped in the remaining part of the Health2000 with 302 knee OA cases and 1700 controls based on the same criterion as in the initial screening.

Phenotype-genotype correlation and role of ancillary investigations in atypical and rare forms of Osteogenesis Imperfecta

M. Balasubramanian[1], *M. J. Parker*[1], *N. J. Bishop*[2];
[1]*Sheffield Clinical Genetics Service, Sheffield, United Kingdom,* [2]*Academic Unit of Child Health, University of Sheffield, Sheffield, United Kingdom.*

Background: Osteogenesis imperfecta (OI) is a heterogeneous group of inherited disorders of bone formation. About 90% of patients have mutations in *COL1A1/ COL1A2*, with an autosomal dominant pattern of inheritance. Other genes are associated with autosomal recessive forms of OI. Other, rare phenotypes have been described.
For this study, patients with phenotypic similarities to Russell-Silver syndrome (RSS) [Parker et al., 2011], OI syndromes (not commonly fitting the Sillence classification) such as Cole-Carpenter and Bruck syndrome and Type V OI were considered. All these conditions were collectively referred to as Atypical OI.
Aims: To investigate individuals with atypical forms of OI, with a view to proposing sub-classifications and identify genotype-phenotype correlations.
Methods: Patients who fulfilled the inclusion criteria were recruited from the Sheffield Clinical Genetics and OI Services. Detailed phenotyping, skin biopsy for histology, including electron microscopy (EM) and collagen species analysis (CSA), skeletal survey, and sequencing of OI genes and aCGH were performed.
Results: Recruited patients (n=14) were phenotypically divided into three sub-groups: Group 1) predominant features of RSS (n=5); Group 2) OI with additional features (n=6); and Group 3) Type V OI (n=3). Common features included poor growth, feeding difficulties, facial dysmorphism +/- fractures. Pathogenic oligogenic mutations were identified in seven patients; chromosomal imbalances in three patients. Skeletal surveys and skin biopsies have revealed common findings. CSA has correlated with molecular findings.
Conclusions: This study has enabled us to sub-classify patients with Atypical OI and established the need for aCGH, skin EM and CSA, routinely in investigating these patients.

Identification of novel COL1A1 gene mutations in Brazilian patients with Osteogenesis Imperfecta

M. V. D. Moraes[1,2], *C. Barbirato*[1,2], *M. G. Almeida*[1,2], *L. Belcavello*[1,2], *M. R. G. O. Rebouças*[3], *V. Sipolatti*[3], *V. R. R. Nunes*[3], *A. N. J. Akel*[3], *M. Zatz*[4], *F. Paula*[1,2];
[1]*Post Graduation Program in Biotechnology, Northeast Network of Biotechnology, Federal University of Espírito Santo, Vitória, Brazil,* [2]*Molecular and Human Genetics Center, Department of Biological Science, Federal University of Espírito Santo, Vitória, Brazil,* [3]*Nossa Senhora da Glória Children's Hospital, Espírito Santo, Vitória, Brazil,* [4]*Human Genome Research Center, University of São Paulo, São Paulo, Brazil.*

Osteogenesis Imperfecta (OI) is a type I collagenopathy that has received great attention in the last decades because of the relevant number of new genes recently related to this disorder. The main symptoms of OI patients are bone fragility and recurrent fractures. Although several new genes have been described for the disease, *COL1A1* and *COL1A2* genes mutations are present in the majority of OI cases. The characterization of mutation pattern among OI genes in patients from different ethnic profile will help us to improve the development of strategies for molecular diagnosis in OI. The goal of this work was to detect the pattern of *COL1A1* gene mutations in OI patients from Espírito Santo, southeast Brazil. A total of 33 unrelated patients were analyzed through a PCR-SSCP screening mutation method and sequencing of abnormal fragments. Patients showed mild, moderate and severe clinical symptoms in 45%, 25% and 30% of the sample, respectively. Two novel frameshift mutations were found in a mild OI case [c.2750delG (p.Gly917AspfsX191)], and a sporadic severe OI [c.3239delC (p.Pro1080LeufsX28)]. We hypothesize that these frameshifts mutations are pathogenics since they can result in abnormal sized protein products with an incorrect amino acid sequence. Furthermore, two missense mutations [c.1138G>T (p.Gly380Cys); c.3235G>A (p.Gly1079Ser)], and three splice site mutations [c.1056+1G>A; c.1875+1G>C; c.2559+1G>A] previously reported were also identified. In conclusion, due to genetic heterogeneity, phenotypic variability and limitations in SSCP technique sensitivity, we strongly support the importance of molecular studies in OI. Financial support: FAPES, FACITEC, and MCTI/CNPq/MEC/CAPES.

FKBP10 gene and recessive Osteogenesis Imperfecta

C. Barbirato[1], *M. V. D. Moraes*[1], *L. Belcavello*[1], *L. S. Almeida*[1], *M. Trancozo*[1], *M. R. G. O. Rebouças*[2], *V. Sipolatti*[2], *V. R. R. Nunes*[2], *A. N. J. Akel*[2], *F. Paula*[1];
[1]*Universidade Federal do Espírito Santo, Vitória, Brazil,* [2]*Hospital Infantil Nossa Senhora da Glória, Vitória, Brazil.*

Osteogenesis Imperfecta (OI) is a very heterogenic genetic disorder with phenotypes that varies from mild to neonatal lethal forms. Most cases of OI are caused by dominant mutations in *COL1A1* and *COL1A2* genes, that codes for the procollagen type I chains. In the last few years, the number of genes related with recessive OI has risen significantly. One of the most recent among them is *FKBP10* gene that codifies a chaperone that interacts with the collagen protein. Our objective was to determine the mutations pattern in *FKBP10* gene from Brazilian patients diagnosed with OI. A total of 26 patients from Espírito Santo (southeast of Brazil) without mutations in *COL1A1* or *COL1A2* genes were analyzed. DNA mutations in *FKBP10* gene were screened using SSCP method and sequencing of abnormal fragments. We detected the c.1546G>A missense change in the exon 9 of *FKBP10* in one of the OI patients. This mutation was not previously described and results in an amino acid change (p.Leu516Phe) into the protein. This mutation was not observed in 90 control samples from the same population. Additional studies are necessary, but we suggest that the p.Leu516Phe mutation may be related with OI in this particularly case. Molecular studies are strongly required because of the great genetic and phenotypic heterogeneity in OI. Thus, these results increase our knowledge about the genetic characteristics in OI and may contribute to the development of more efficient methods to diagnose and treat OI patients. Financial support: FAPES, FACITEC, and MCTI/CNPq/MEC/CAPES.

Osteogenesis Imperfecta Type V with Hyperplastic Callus, a clinical and molecular review of 9 cases

G. Baujat[1], *M. Le Merrer*[1], *S. Dos Santos*[1], *G. Pinto*[1], *J. P. Bonnefont*[1], *C. Cormier*[2], *G. Finidori*[1], *S. Naudion*[3], *Z. Pejin*[1], *A. Munnich*[1], *V. Cormier-Daire*[1], *A. Lebre*[1];
[1]*Hôpital Necker-Enfants malades, Paris, France,* [2]*Hôpital Cochin, Paris, France,* [3]*Hôpital Universitaire Pellegrin, Bordeaux, France.*

The Osteogenesis Imperfecta (OI) group includes various heritable diseases of the extracellular bone matrix, characterized by low bone mass, variable deformities and high fractures incidence. Among them, OI type V is characterized by propensity to hyperplasic callus formation, calcification of the forearm interosseous membrane and radial head dislocation. This dominant inherited OI subtype is associated with a specific histopathologic pattern. Recently, the recurrent c.14 C>T mutation was identified in IFITM5 gene as the unique molecular cause of OI type V in all patients.
We describe here 9 patients from 7 families, regularly followed in Necker-Enfants malades Hospital with OI type V (age: 6 months-38 years). In all cases, OI was caused by the c.-14C>T mutation in *IFITM5*. 6/ 9 patients presented with a severe form of OI, with a progressive evolution leading to significant mobility impairment and wheelchair in 4/6 older cases. The age of first fracture was early in all cases (between birth and 2.5years). By contrast, the number of fractures (from 6 to > 60) and age of the first hyperplastic callus varied widely (between 3 months and 13 years). The adult height ranged from 1.30 to 1.50 meter. Scoliosis was noted in 4 cases. Surprisingly, persistent alkaline phosphatase without D vitamin defect was noted in 3 cases. The study confirms the clinical variability, and further describes the clinical and radiological evolution under medical (bisphosphonates, anti-inflammatory) and surgical (intramedullary rods, vertebral arthrodesis) treatments.

Autosomal recessive osteogensis imperfecta (OI) was diagnosed in three unrelated Israeli Bedouin consanguineous families. Fractures were evident in all cases in infancy. Genome wide linkage analysis ruled out association with any of the known OI genes, and identified a single homozygosity locus of ~2 Mb on chromosome 9 common to all affected individuals (maximum multipoint lod score 6.5). Whole exome sequencing identified only a single mutation within this locus that was shared by all affected individuals: a homozygous deletion mutation of exon 4 of TMEM38B, leading to an early stop codon and a truncated protein, as well as low TMEM38B mRNA levels. TMEM38B encodes TRIC-B, a ubiquitous component of TRIC, a monovalent cation-specific channel involved in Ca2+ release from intracellular stores that has been shown to act in cell differentiation. Molecular mechanisms through which a TMEM38B mutation might lead to an OI phenotype are yet to be explored.

Osteogenesis imperfecta (OI) is a heritable brittle bone disorder with high clinical variability. Dominant forms are mostly due to heterozygous mutati-

ons in a type I procollagen gene (*COL1A1/COL1A2*). In recessive OI the underlying mutations often affect type I collagen processing or chaperoning. A small proportion of OI cases still remains molecularly unexplained.
We identified mutations in two novel genes for human OI in two separate families. In family 1, candidate gene analysis revealed a homozygous genomic deletion of CREB3L1 in the affected siblings. *CREB3L1* encodes OASIS, an endoplasmatic reticulum (ER)-stress transducer that intranuclearly regulates procollagen type I expression upon processing by regulated intramembrane proteolysis during murine bone formation. In family 2, with three affected foetuses and six healthy siblings, genome-wide linkage analysis and exome sequencing revealed a homozygous acceptor-splice site mutation in *TAPT1* (*Transmembrane Anterior Posterior Transformation-1*), that causes an in-frame deletion of the highly conserved exon 10. *TAPT1* has been reported in the context of murine skeletal patterning.
In both defects, type I (pro)collagen posttranslational modification was grossly preserved, but secretion was delayed in *TAPT1* mutated fibroblasts. Similarly to OASIS, immunocytochemistry localized TAPT1 to the ER, and *TAPT1* expression was upregulated upon ER stress. Moreover, both genetic defects demonstrate alterations in the ER stress response pathways with nearly absent expression of CHOP and XBP1.
In conclusion, *CREB3L1* and *TAPT1* are two novel genes for human recessive OI. Mutations in both genes similarly affect the normal ER stress response that links to type I collagen production.

P01.032
Osteomalacia as a key feature of Raine syndrome: changing the paradigm.

*V. Faundes[1], P. Gonzalez-Hormazabal[2], **S. Castillo Taucher**[1,3], A. Crosby[4], A. Maturana[5];*
[1]Sección Genética, Hospital Clínico Universidad de Chile, Santiago, Chile, [2]Programa de Genética Humana, Instituto de Ciencias Biomédicas, Universidad de Chile, Santiago, Chile, [3]Laboratorio de Citogenética, Clínica Alemana, Santiago, Chile, [4]Genetics Research Centre, St. George's University London, London, United Kingdom, [5]Servicio de Neonatología, Clínica Alemana, Santiago, Chile.

INTRODUCTION: Raine syndrome is a skeletal dysplasia characterised mainly by osteosclerosis of bones, facial dysmorphism, and a course frequently lethal. However, we present the first alive case molecularly confirmed whose radiographs showed osteomalacia. **CASE REPORT:** The patient was born at 26 weeks of gestation to non-consanguineous and healthy parents, due to intrauterine growth retardation and worsening of Doppler examination. His birth parameters were all p<2, and albeit delivery and Apgar scores were normal, he subsequently suffered from different premature birth complications. Furthermore, at 70 days old bilateral forearm spontaneous fractures were suspected and confirmed, whereas follow-up radiographs revealed broad epiphyses and thin diaphyses of long bones, accompanied of generalised osteomalacia. At physical examination, the patient had some dysmorphic characteristics which suggest Raine syndrome such as ocular proptosis, hypertelorism, slightly downslanted palpebral fissures, broad nasal bridge, midface hypoplasia, micrognathia and short limbs and fingers. Karyotype was normal, and although his cerebral ultrasounds were normal, renal echography revealed nephrocalcinosis. One year later, his health status has improved substantially, specially his osteomalacia and nephrocalcinosis. Parallelly, *FAM20C* sequencing analysis was performed, which demonstrated the heterozygous duplication g.286470_286503dup34 and heterozygous SNP rs192542992, which is present just in 0.7% of the population. *In silico* analysis of these findings showed rupture of splicing site of exon 4, and the creation of a new splicing regulatory element, respectively. **CONCLUSION:** Although these results should be confirmed experimentally, it seems that osteomalacia is also a key feature of Raine syndrome, in concordance with the recently published murine model.

Abnormal Type I Collagen Glycosylation Pattern and Cross-linking in a Cyclophilin B KO Mouse Model of Recessive Osteogenesis Imperfecta

W. A. Cabral[1], *I. Perdivara[2], M. Weis[3], M. Terajima[4], A. R. Blisset[1], W. Chang[1], E. Makareeva[5], S. Leikin[5], D. R. Eyre[3], M. Yamauchi[4], J. C. Marini[1];*
[1]Bone and Extracellular Matrix Branch, NICHD, NIH, Bethesda, MD, United States, [2]Laboratory of Structural Biology, NIEHS, NIH, Research Traingle Park, NC, United States, [3]Orthopaedic Research Laboratories, University of Washington, Seattle, WA, United States, [4]NC Oral Health Institute, University of North Carolina, Chapel Hill, NC, United States, [5]Section on Physical Biochemistry, NICHD, NIH, Bethesda, MD, United States.

Recessive osteogenesis imperfecta (OI) is caused by mutations in genes encoding proteins involved in post-translational interactions with type I collagen. Types VII-IX OI involve defects in the collagen proly 3-hydroxylation complex, which modifies α1(I)Pro986. Cyclophilin B, encoded by *PPIB*, is a complex component with PPIase activity that facilitates collagen folding. To investigate the role of CyPB in collagen post-translational modifications and crosslinking, we generated a *Ppib* KO mouse using gene-trap technology. *Ppib* expression is absent in skin, fibroblasts, femora, and calvarial osteoblasts; only residual (<11%) α1(I)P986 3-hydroxylation is detectable in cell cultures, skin and bone tissues. Collagen from KO cells has delayed electrophoretic mobility, consistent with delayed intracellular folding in cell culture assays. However, total collagen 5-lysyl and prolyl 4-hydroxylation was normal, suggesting altered glycosylation in KO. We demonstrated that, except for lysyl residues involved in crosslinking, most helical residues of KO collagen have increased diglycosylation. Although total bone collagen crosslinks (HP+LP) in KO were double WT (p=0.003), abnormal modification is associated with a 70-80% reduction of collagen deposited into KO matrix. We detected a 4-fold increase in trivalent LP crosslinks (p=0.001) and corresponding decrease in the HP/LP ratio, due to reduced hydroxylation of helical crosslink residues in KO bone. This *Ppib* KO mouse recapitulates the OI type IX phenotype including delayed collagen folding, and smaller long bones with significantly reduced BMD, BV and TbN. The finding that collagen crosslink patterns are shifted to trivalent forms lacking helical Hyl may contribute to decreased collagen matrix deposition and bone strength.

Russell-Silver syndrome and preaxial polydactyly

G. Morin[1], *A. Irani[2], K. Braun[3], T. Dery[1], G. Jedraszak[1], B. Demeer[1], I. Netchine[4], B. Boudailliez[3], J. Gondry[5], M. Mathieu[1];*
[1]Clinical Genetic Unit, Amiens, France, [2]Neonatology Unit, Beauvais, France, [3]Pediatric Endocrinology, Amiens, France, [4]Endocrinology Laboratory - Trousseau Hospital, Paris, France, [5]Prenatal Diagnosis Centre, Amiens, France.

Russell-Silver syndrome is a growth disorder characterized by pre and postnatal growth restriction, conserved head circumference, distinctive facies and body asymmetry. Its molecular mechanisms are complex including maternal disomy of chromosome 7 for less than 10% of cases and methylation defect of the 11p15 chromosomal region for the majority of them. Among skeletal anomalies, short stature, short arms, fifth fingers clinodactyly, short and stubby fingers and toes are usual. We report here a case of Russell-Silver syndrome associated with unilateral preaxial polydactyly.

This male patient was born at 37 weeks of amenorrhea, after a pregnancy characterized by IUGR and unilateral kidney agenesis. Prenatal karyotype on amniotic cells was unremarkable and array-cgh without imbalance. At birth, weight was 1400g, height was 36.5cm and OFC 33.5cm. Facies was triangular with broad forehead, naevus flammeus, small pointed chin, small philtrum angioma. He had bilateral fifth fingers clinodactyly, moderate hypospadias and right thumb duplication. Renal ultrasound examination showed a horseshoe kidney. The presence of demethylation of the H19 locus confirmed the diagnosis of Russell-Silver syndrome.

The association of Russell-Silver syndrome and preaxial polydactyly is unusual. To our knowledge, it was reported only one time in a 4-year-old boy presenting with marked language delay and uniparental maternal disomy of chromosome 7 (Potgieter 2000). With a frequency of preaxial polydactyly in the general population of 1 in 3000 births, a simple coincidence cannot be rule out. However, a real association is possible with Russell-Silver syndrome, particularly with these 2 different molecular mechanisms.

Results of longstanding clinical observation of siblings with Sensenbrenner syndrome

A. Latos-Bieleńska[1,2], *D. Zwolinska*[3], *J. Walczak-Sztulpa*[1];
[1]*Department of Medical Genetics, University of Medical Sciences, Poznań, Poland,* [2]*Center for Medical Genetics GENESIS, Poznan, Poland,* [3]*Department and Clinic of Paediatric Nephrology, Medical University, Wroclaw, Poland.*

Sensenbrenner syndrome (cranioectodermal dysplasia, CED) is a very rare autosomal recessive ciliopathy, characterized by craniofacial, skeletal, and ectodermal abnormalities. About 40 cases have been described to date. CED is a heterogeneous genetic disorder and recently four genes: *IFT122(WDR10)*, *IFT121(WDR35)*, *IFT43(C14ORF179)* and *IFT144(WDR19)*, have been identified (all encoding proteins that are part of the intraflagellar transport complex A, IFTA). IFTA is involved in retrograde ciliary transport, which returns proteins from the tip of the cilia to the cell body and pays an import role in the assembly and maintenance of cilia structure.
Here we report on a 11-year-old girl and her 7-year-old brother with CED. Their healthy parents are distantly consanguineous. Molecular analysis revealed a homozygous missense mutation p.V553G (c.T1658G) in the *IFT122* gene. Clinical features included short stature with rhizomelic shortening of limbs, brachydactyly, narrow chest, craniosynostosis, dolichocephaly, high forehead, full cheeks, telecanthus, broad nasal bridge, low-set prominent ears, small and widely spaced teeth, dysplastic auricles, fine sparse hair, abnormal nails, bilateral inguinal hernia, skin laxity. Mental development is normal. Both children suffer from tubulointerstitial nephropathy with more severe features in the brother (kidney transplantation at the age of 7 was necessary). We present changing phenotype of the sibs during long clinical observation.

We describe multiple affected individuals from two families of Arab Moslem origin with a distinctive syndrome of severe short stature, peculiar facial and other clinical features, with autosomal recessive mode of inheritance. The affected individuals have pre and post- natal growth retardation, which manifests probably as early as the second trimester of pregnancy. Typical skeletal changes included short long bones especially of the femurs, humerii and hands, with mild metaphyseal changes and very short femoral necks.
Homozygosity mapping located the disease gene to 3p21.1-3p21.31. Using whole exome sequencing analysis complemented with Sanger direct sequencing, we identified a homozygous point mutation (p.Leu171Pro) in *POC1A* (Centriolar Protein Homolog A), that co-segregate with the disease phenotype in two families. The mutation affects a highly conserved amino acid residue and is predicted to interfere with protein function. Poc1, POC1A homolog, had previously been found to have a role in centrosome stability in unicellular organisms. Accordingly, although centrosome structure was preserved, the number of centrosomes and their distribution was abnormal in affected cells. In addition, the Golgi apparatus presented a dispersed morphology and cholera toxin trafficking from the plasma membrane to the Golgi was aberrant, with accumulation in large vesicles in the cytosol. Our data underscore the importance of POC1A for proper bone, hair and nail formation as well as the importance of normal centrosome in Golgi assembly and trafficking from the plasma membrane to the Golgi apparatus.

Collagen deregulation in the glenohumeral capsule of patients with anterior shoulder instability

M. F. Leal, *P. S. Belangero, G. E. Machado, A. C. Pochini, M. A. C. Smith, C. V. Andreoli, S. I. Belangero, B. Ejnisman, M. Cohen;*
Federal University of São Paulo, São Paulo, Brazil.

Anterior shoulder instability is a common orthopedic problem among young athletes. After a traumatic shoulder dislocation, patients present capsular laxity. Molecular modifications in the glenohumeral capsule may be associated with this injury. Here, we aimed to evaluate the *COL1A1*, *COL1A2*, *COL3A1*, and *COL5A1* expression in traumatic anterior shoulder instability. Collagen gene expression was analyzed by real-time quantitative PCR in the antero-inferior, antero-superior, and posterior portions of the shoulder capsule from 33 patients with traumatic anterior shoulder instability and 5 individuals with acromioclavicular injury (controls). We observed an increased expression of *COL1A1* and *COL3A1* in the antero-superior region (P=0.038 and P=0.034, respectively) and of *COL1A2* in the posterior portion (P=0.043) of glenohumeral capsule of shoulder instability patients compared with the controls. Concerning the clinical data, patients who had experienced more than 1 year of shoulder instability demonstrated reduced expression of *COL1A1* in the antero-inferior and in the posterior regions compared with patients with less than 1 year of symptoms (P=0.014 and P<0.001, respectively). In the antero-inferior portion, reduced expression of *COL5A1* was associated with recurrent shoulder dislocation compared with a single dislocation episode (P=0.049). Reduced *COL1A1* was also associated with recurrent shoulder dislocation in the posterior region (P=0.006). Thus, collagen expression was deregulated in the three evaluated portions of the glenohumeral capsule of shoulder instability patients which may be related to the capsular laxity. Since there is a reciprocal load-sharing relationship in the capsule, these modifications in distinct portions of the capsule may reflect a compensatory mechanism after a dislocation episode.

Severe brachydactyly and absent ossification of several tubular bones in hands and feet as distinctive features of a rare skeletal dysplasia

G. Mortier[1], *E. Steenackers*[1], *M. Vaerenberg*[2], *K. Nieuwinckel*[2], *B. Albrecht*[3], *G. Gillessen-Kaesbach*[4], *G. Vandeweyer*[1], *W. Van Hul*[1];
[1]*University of Antwerp, Antwerp, Belgium,* [2]*Sint-Joseph Hospital, Bornem, Belgium,* [3]*Universitätsklinikum Essen, Essen, Germany,* [4]*Universität zu Lübeck, Lübeck, Germany.*

We report on a boy with a generalized skeletal dysplasia characterized by severe brachydactyly and pronounced growth failure. The proband is the first child of healthy parents originating from the same village in Macedonia. A non-lethal skeletal dysplasia was suspected on prenatal ultrasound. The boy was born at 36 weeks with a weight of 1990 g, length of 36.5 cm and head circumference of 30.5 cm. He did not require assisted ventilation in the neonatal period. On follow-up a severe growth failure became apparent. The last clinical evaluation at the age of 9 months revealed a weight of 2510 g and a length of 52.4 cm. He has a relatively large head with frontal bossing, bluish sclerae, redundant and soft skin and very tiny fingers and toes. In the literature only 5 other cases with a similar phenotype have been described. All patients died during the first year of life. They share a similar and unusual pattern of ossification defects in hands and feet. Two pairs of affected sibs suggest an autosomal recessive inheritance. Whole exome sequencing in the proband revealed a list of 37 homozygous, non-synonymous variants not annotated in databases of common variation. Eleven variants were predicted to have a deleterious impact on the protein. Although none of these variants involve genes that have been associated with a known skeletal dysplasia, some are interesting to further explore since they are either associated with limb development or play a role in growth and cell cycle regulation.

Rare cases with skeletal dysplasia - Romanian experience. Diagnosis based on clinical and radiographic correlations

V. Plaiasu, *D. Ochiana, G. Motei, F. Brezan, N. Iagaru;*
IOMC Prof.dr.Alfred Rusescu, Bucharest, Romania.

Skeletal dysplasias represent a group of more than 400 conditions which affect cartilage and bone growth, defined by molecular, biochemical and ra-

diographic criteria, included in 40 different groups, after the last Revision of Nosology and Classification of Genetic Skeletal Disorders. Although individually rare or very rare, collectively there are many patients with these congenital disorders.
Clinical evaluation is the fundation upon which any suspicion of skeletal dysplasia is built. X-ray films are all that are needed to identify a particular diagnosis in most cases. Suspected cases of skeletal dysplasias involves systematic imaging of the long bones, thorax, hands and feets, skull and spine.
Our Medical Genetics Department provides evaluation from clinical and radiological point of view, diagnosis and counselling for children with skeletal dysplasia and their families. In this work we present selected cases with bone dysplasias, some of them very rare, from our clinic day experience: achondroplasia, osteogenesis imperfecta, lysosomal storage disorders with skeletal involvement, geleophysic dysplasia, Camurati-Engelmann disorder, Conradi-Hünermann syndrome, Ellis-van Creveld syndrome, short rib-polydactyly, nail-patella syndrome, metaphyseal dysplasias, multiple epiphyseal dysplasia, Langer-Giedon syndrome, Proteus-like syndrome etc. Clinical summary of the patients, including the pedigree, clinical photographs and X-rays are presented, focussing on diagnostic issues for each condition.
Because of their variety, skeletal dysplasias remain a diagnostic challenge. Clinical exam and radiological findings represent the key for the recognition of a skeletal dysplasia condition from the long list of genetic skeletal disorders and for the pre-test counselling.

Small Patella Syndrome : new *TBX4* mutations and literature review

F. Escande[1], *C. Vanlerberghe*[2], *F. Petit*[2], *A. S. Jourdain*[1], *A. Dieux*[2], *A. Toutain*[3], *S. Jacquemont*[4], *A. Ferrarini*[4], *N. Boutry*[5], *M. Holder*[6,2], *S. Manouvrier*[2];
[1]*Service de biologie moléculaire, Centre de Biologie et Pathologie, CHRU, Lille, France,* [2]*Service de génétique clinique Guy Fontaine, Hôpital Jeanne de Flandre, CHRU, Lille, France,* [3]*Service de génétique clinique, CHU, Tours, France,* [4]*Service de génétique clinique, CHU Vaudois, Lausanne, Switzerland,* [5]*Service de radiologie pédiatrique, hôpital Jeanne de Flandre, CHRU, Lille, France,* [6]*Clinical Genetics Department, Guy's hospital, London, United Kingdom.*

Small patella syndrome (SPS), also called ischiopatellar dysplasia, coxopodopatellar or ischio-pubic-patellar syndrome (OMIM 147891), is characterised by patellar agenesis or hypoplasia, abnormal ossification of the ischio pubic junction and feet abnormalities, comprising an enlarged space between the 1st and 2nd toes (sandal gap), short 4th and 5th rays and pes planus. This rare autosomal dominant disorder is caused by mutations in *TBX4*, known to be involved in hindlimb development and outgrowth. Here, we describe four families presenting with SPS, and a *TBX4* mutation has been identified in three of them. One mutation had been previously reported: c.1112dupC (p.Pro372SerfsX14), whereas the two others had not been yet identified: c.1062T>G (p.Tyr354X) and c.(?_-45)_(401+?)del (an intragenic deletion of *TBX4*'s first three exons). In addition to SPS's common features, our patients presented with some minor associated findings such as syndactyly of the 2nd and 3rd toes, dental anomalies and/or hip dysplasia. We compare their phenotypes to those of previously described patients, who had been molecularly characterised or not, in order to underline the expression variability of SPS. Furthermore, we discuss if the associated minor features could also be explained by *TBX4* mutations. Since SPS is a rare condition, achieving a better clinical description and establishing correlations with the genotype might help towards an earlier diagnosis and an appropriate medical management.

Split hand/split foot malformation type 6 in multiple consanguineousOmani family with a novel homozygous mutation in *WNT10B* gene providingfurther evidence of recessive inheritance in SHFM

A. Al-Kindy, *F. Al-Murshedi, Z. Bruwer;*
Sultan Qaboos University Hospital, Muscat, Oman.

Split hand/split foot malformation (SHFM) is a rare isolated congenital limb malformation, characterized by a deep median cleft of the hand and/or foot due to the absence of the central rays and aplasia/or hypoplasia of the phalanges, metacarpals and metatarsals. SHFM6 (OMIM # 225300) is the rarest among familial SHFM subtypes and is inherited in an autosomal recessive manner. It has wide clinical variability including isolated cutaneous syndactyly and even non-penetrance and should be excluded in seemingly sporadic cases. Clinical variability also exists between limbs of a single individual. We describe the variable clinical and morphologic features of four affected individuals with SHFM6 in a highly inbred Omani family. The first two female siblings have the classical phenotype with asymmetrical involvement of both hands and feet with ectrodactyly, oligodactyly, syndactyly, absent carpal and tarsal bones. In contrast, their two double first cousins, a boy and a girl, present mildly with only cutaneous syndactyly of the feet. This is the first case report of an Omani family with SHFM6 with a novel homozygous mutation c.290T>C p.Leu97Pro in exon 3 of WNT10B gene. The limb malformations required multiple surgeries for cosmetic and functional corrections and had profound psychosocial impact and stigma in this family such that they opted for preimplantation genetic diagnosis.

P01.042

A novel role of MARP proteins in intercellular communication

A. R. Nestorovic[1], *J. Jasnic-Savovic*[1], *L. Rakicevic*[1], *D. Radojkovic*[1], *G. Faulkner*[2], *S. Kojic*[1];
[1]*IMGGE, University of Belgrade, Belgrade, Serbia,* [2]*CRIBI, University of Padova, Padova, Italy.*

The MARP family members Ankrd1/CARP and Ankrd2/ARPP are components of the sarcomeric I band mechanosensory complex in both cardiac and skeletal muscles, where they bind N2A region of titin. In response to mechanical stimuli they shuttle to the nucleus, acting as messengers in stress response pathways. Since they are altered in a number of neuromuscular and cardiovascular disorders, as well in some tumors such as rhabdomyosarcoma, renal oncocytoma and ovarian cancer their potential role as diagnostic and/or prognostic markers is under the study. Recently, regulatory role of Ankrd2/Arpp was corroborated demonstrating its ability to bind signaling proteins that contain PDZ motifs. Here, using protein array methodology, we have identified 10 PDZ proteins that directly interact with Ankrd1/CARP. Moreover we have confirmed its interaction with Zonula Occludens 1 (ZO-1) employing in vitro binding assay. Apart from p53, titin and calpain 3, ZO-1 represents a novel common partner for both MARPs. ZO proteins are localized at tight junctions and establish a link between the transmembrane components and the perijunctional cytoskeleton at cell-cell contacts. They are delocalized or down-regulated in several types of carcinomas: breast cancer, primary and metastatic pancreatic cancer and brain microvascular endothelial cells from human brain tumors. Interaction with ZO-1 suggest possible role of Ankrd1/CARP and Ankrd2/Arpp in intercellular communication. The functional interplay between MARPs and tight junction proteins could have potential role in mechanisms involved in triggering malignant transformation.

Split hand/foot malformation (SHFM) with long bone deficiency (SHFLD, MIM#119100) is a rare condition characterized by SHFM associated with long-bone malformation usually involving the tibia. Previous published data reported several unrelated patients with 17p13.3 duplication and SHFLD. Recently, *BHLHA9* duplication has been identified to be responsible for this limb malformation. No mutation has been reported so far. We described 13 families affected with ectrodactyly harbouring a *BHLHA9* duplication, identified either by array-CGH or quantitative PCR. Affected patients present with isolated limb malformations. Hands defects consisted usually in uni- or bilateral ectrodactyly. Syndactyly or monodactyly were infrequent findings. Long bone deficiency was present in 41% of the affected patients, being a specific finding regarding which BHLHA9 duplication testing should be addressed. This defect concerned the tibia in most cases, and infrequent-

ly the radius or the femur. As reported before, pedigrees show incomplete penetrance of BHLHA9 duplication, and high intrafamilial and intraindividual variability.

P01.044
Vitamin- D deficiency and Familial Brachydactyly mimicking Pseudohypoparathyroidism (PHP)

M. A. Soylemez;
Marmara University Medical School, Istanbul, Turkey.

OBJECTIVE:Vitamin D deficiency is not a rare disorder. The Endocrine Society recommends levels >30 ng/mL for good health. Pseudohypoparathyroidism (PHP) is a rare disorder characterized by parathyroid hormone (PTH) resistance with (type 1a) or without (type 1b) the Albright Hereditary Osteodystrophy (AHO) phenotype of short stature, brachydactyly, and mental retardation [2]. Patients with PHP have elevated PTH levels. However, the same laboratory values can also be seen in children or adults with vitamin D deficiency, and diagnostic confusion is common. We report three cases of vitamin D deficiency and familial brachydactyly with presentations suggestive of PHP.
Case Presentation: We report a family with 3 affected members in three generations confirming autosomal dominant inheritance and variable expressivity of short metacarpals and metatarsals (Figure-1). Biochemical results are evaluated. All patients revealed high PTH and low Vitamin D levels (Table-1). Short metacarpals and metatarsals are frequent findings in brachydactyly type E. Poznanski *et al*. [1] concluded that ,brachydactyly E is radiologically indistinguishable from the PHP syndrome. Elevated PTH levels are treated with vitamin- D replacement therapy. Correction of Vitamin D deficiency resulted in a return to normal range of PTH levels in whole patients (Table-2).
*Conclusions:*We report a case of co-existence of brachydactyly and vitamin D deficiency for the first time in the literature. After correction of vitamin D deficiency, Parathormon levels returned to normal range, which in return prevented misdiagnosis. Geneticists should be more careful about diagnosis of PHP syndrome. Otherwise, a chance of therapy and preventing hyperparathyroidism complications will be missed.

P01.045
Mutations in *ECEL1* cause distal arthrogryposis type 5 with ophthalmoplegia

*S. Shaaban[1,2,3], **F. DUZCAN**[4,5], C. Yildirim[4], W. Chan[1,6], C. Andrews[1,6], N. Akarsu[7], E. Engle[1,3,6];*
[1]Children's Hospital, Boston, MA, United States, [2]Dubai Harvard Foundation for Medical Research, Boston, MA, United States, [3]Harvard Medical School, Boston, MA, United States, [4]Faculty of Medicine, Pamukkale University, Denizli, Turkey, [5]Pamukkale University Hospital, Denizli, Turkey, [6]Howard Hughes Medical Institute, Chevy Chase, MD, United States, [7]Faculty of Medicine, Hacettepe University, Ankara, Turkey.

Using a combination of homozygosity mapping and whole-exome sequencing, we identified a novel mutation in the endothelin-converting enzyme-like 1 (*ECEL1*) gene in a consanguineous

pedigree of Turkish origin presenting with camptodactyly, scoliosis, limited knee flexion, severe myopia, facial weakness and ophthalmoplegia. The missense c.1819 G>A mutation results

in the substitution of serine for the highly conserved glycine at residue 607 of ECEL1. *ECEL1* mutations were recently reported to cause recessive forms of distal arthrogryposis without ophthalmoplegia. Distal arthrogryposis is most commonly inherited as a dominant trait with reduced penetrance and variable expressivity. This report expands on the molecular basis and the phenotypic spectrum of *ECEL1*-associated congenital contracture syndromes.

A genome wide association study in dogs reveals a new candidate gene for human chondrodysplasias

K. Kyöstilä[1,2,3], *A. K. Lappalainen[4], H. Lohi[1,2,3];*
[1]Research Programs Unit, Molecular Neurology, University of Helsinki, Helsinki, Finland, [2]Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland, [3]Department of Molecular Genetics, Folkhälsan Institute of Genetics, Helsinki, Finland, [4]Department of Equine and Small Animal Medicine, University of Helsinki, Helsinki, Finland.

Similar to humans, dogs suffer from different types of genetic skeletal disorders affecting the bone and cartilage tissues. We have established pedigrees and sample cohorts of two dog breeds that suffer from an autosomal recessive chondrodysplasia. The affected dogs present with a disproportionate short stature dwarfism of varying severity. Radiographic examination of two affected animals revealed from mild to severe skeletal changes, including curvature of radii and ulnae, metaphyseal flaring and misshapen femoral heads and necks. A genome wide association study in a cohort of nine affected and nine healthy dogs mapped the disease to a 2-Mb region on canine chromosome 17 using a canine 22K SNP chip. The associated locus contained a promising cartilage-specific candidate gene that was screened for possible disease causing mutations. Sequencing of all the coding regions revealed a nonsense mutation that segregated fully with the recessive disease in both breeds. The encoded protein is known to be expressed in cartilage chondrocytes and to be involved in the process of endochondral ossification. As a consequence of the nonsense mutation, the protein is severely truncated and was not detected in the affected cartilage tissue. Our study describes a large animal model to further examine the role of the gene in growth plate function. The mutated gene has not been reported in human chonrodysplasias and thus represents a novel candidate for human patients. Meanwhile, a genetic test enables the eradication of the condition in the affected breeds.

A novel ARSE mutation in a patient with chondrodysplasia punctata 1 and in his mother with low frequent somatic and/or germline mosaicism detected by deep sequencing using NGS

T. KANAME[1], *K. Kurosawa[2], K. Yanagi[1], K. Naritomi[1];*
[1]University of the Ryukyus, Nishihara-cho, Japan, [2]Kanagawa Children's Medical Center, Yokohama, Japan.

Chondrodysplasia punctata 1 (CDPX1) is an X-linked recessive disorder characterised by punctate calcifications in radiographs of the feet and other sites, nasomaxillary hypoplasia and brachytelephalangy. It is known that mutations of the *arylsulfatase E* (*ARSE*) gene affect the disorder.
We met a male patient clinically diagnosed with CDPX1. Examination of the *ARSE* gene by Sanger sequencing for all exons in the patient revealed a missense mutation, c.266G>A (p.S89N). The mutation was not found in 250 healthy controls. Prediction of functional effects of the substitution by PolyPhen-2 and SIFT displayed that the mutation affects the protein function.
In order to confirm whether his mother is carrier, the molecular test was done as well. However, the Sanger sequencing could not detect the mutation in the mother, suggesting that the mutation was de novo. However, since there is no report of de novo mutation in CDPX1 patients, there was a possibility that the mother had a germline mosaicism and/or somatic mosaicism.
Thus, we performed deep sequencing of the *ARSE* gene in the mother using GS Junior, next generation sequencer, resulted that the mother had a somatic mosaicism of the mutation in the blood cells at a ratio of 11%.
We concluded that the deep sequencing using NGS could detect low frequent mosaicism, which might be a part of germline mosaicism, and should be performed in patient's parents with such 'de novo' mutation to make reliable genetic counselling.

P01.048
Founder effects in Galician (NW Spain) lamellar ichthyosis families

L. Fachal[1], *L. Rodríguez-Pazos[2], M. Ginarte[2], J. Toribio[2], A. Salas[3], A. Vega[1];*
[1]Fundación Pública Galega de Medicina Xenómica-SERGAS. Grupo de Medicina Xenómica-USC, CIBERER, IDIS, Santiago de Compostela, Spain, [2]Department of Dermatology, Complejo Hospitalario Universitario, SERGAS, Faculty of Medicine, Santiago de Compostela, Spain, [3]Unidade de Xenética, Instituto de Medicina Legal, Facultade de Medicina, and Departamento de Anatomía Patolóxica e Ciencias Forenses, Facultade de Medicina, Santiago de Compostela, Spain.

Mutations in transglutaminase 1 gene (TGM1) are a major cause of la-

mellar ichthyosis. Three mutations, c.2278C>T, c.1223_1227delACAC and c.984+1G>A, were observed at high frequency (~46%, ~21% and ~13% of all TGM1 gene mutations, respectively) in 11 non-consanguineous Galician (NW Spain) ichthyosis families.
We aimed to determine whether these mutations were inherited from a common ancestor, and to estimate the number of generations since their initial appearance. We carried out a haplotype-based analysis of a region 12 Mb. encompassing TGM1. Haplotype reconstruction from unphased genotypes of the members of the affected families showed that all carriers for each of the mutations harbored the same haplotypes, indicating common ancestry. Two linkage disequilibrium based methods were used to estimate the time to the most recent common ancestor (TMRCA), while a Bayesian-based procedure was used to estimate the age of the two most frequent mutations.
In good agreement with the documentation record and the census, both mutations arose between 2,800-2,900 years ago (y.a.), but their TMRCA was in the range 600-1,290 y.a., pointing to the existence of historical bottlenecks in the region followed by population growth. This demographic scenario finds further support on a Bayesian Coalescent Analysis based on TGM1 haplotypes that allowed to estimate the occurrence of a dramatic reduction of effective population size occurring around 900-4,500 y.a. (95% highest posterior density) followed by exponential population growth.
This work was funded by a grant from the Ramon Areces Foundation given to AV.

Myhre syndrome-causing SMAD4 mutations result in disorganization of extracellular matrix that is corrected by losartan treatment.

P. Piccolo[1], *P. Mithbaokar*[1], *V. Sabatino*[1], *J. Tolmie*[2], *M. Schiaffino*[3], *M. Filocamo*[4], *D. Melis*[5], *G. Andria*[5], *N. Brunetti-Pierri*[1,5];
[1]Telethon Insitute of Genetics and Medicine, Naples, Italy, [2]Ferguson-Smith Department of Clinical Genetics, Yorkhill Hospital, Glasgow, United Kingdom, [3]Clinica Pediatrica, Istituto G. Gaslini, Genoa, Italy, [4]Centro di Diagnostica Genetica e Biochimica delle Malattie Metaboliche, Istituto G. Gaslini, Genoa, Italy, [5]Department of Translational Medical Sciences, Federico II University of Naples, Naples, Italy.

Myrhe syndrome (MS, MIM 139210) is an autosomal dominant disorder presenting with short stature, laryngotracheal stenosis, brachydactyly, generalized muscle hypertrophy, joint stiffness, thick skin, and a distinctive facies. Cognitive disability and cardiac involvement are also frequently reported. Recently, recurrent mutations affecting codon Ile500 of *SMAD4* gene have been found in patients with MS. Mutations in this residue result in perturbation of expression in both TGF-β and BMP target genes that are involved in extra-cellular matrix (ECM) homeostasis.
In this study, we investigated the functional consequences of *SMAD4* mutations and the efficacy of TGF-β signaling antagonist losartan for correction of ECM defect in four MS fibroblast cell lines harboring the p.Ile500Val mutation and the p.Arg496Cys mutation. Western blot analysis showed increased SMAD4 levels in MS fibroblasts. Compared to control cells, MS fibroblasts showed upregulation of *MMP2* and downregulation of *SERPINE1* genes, suggesting an imbalance in protease/inhibitors ratio. Based on these findings, we hypothesized an impaired ECM deposition that was confirmed by reduced length and thickness of fibrillin microfibrils in MS fibroblasts compared to controls. Because disruption of microfibril network results in increased bioavailability of TGF-β, we investigated whether losartan is effective at improving ECM deposition in MS cells. We found that losartan treatment improved microfibril thickness and networking compared to vehicle-treated fibroblasts, normalized phosphorylated SMAD2 protein levels, and *MMP2* and *SERPINE1* mRNA levels. In conclusion, the results of these studies suggest that losartan might be a good drug candidate for treatment of connective tissue manifestations in MS.

Nager syndrome: report on 11 families and confirmation of SF3B4 haploinsufficiency as the major cause

A. Jourdain[1], *F. Escande*[1], *N. Porchet*[1,2], *J. Amiel*[3], *B. Doray*[4], *M. Delrue*[5], *E. Flori*[4], *S. Marlin*[6], *S. P. Robertson*[7], *S. Manouvrier-Hanu*[1,2], *M. Holder-Epinasse*[1,2,8], *F. M. Petit*[1,2];
[1]CHRU de Lille, LILLE, France, [2]Université Lille Nord de France, Lille, France, [3]CHU Necker-Enfants Malades, PARIS, France, [4]CHU de Strasbourg, STRASBOURG, France, [5]CHU de Bordeaux, BORDEAUX, France, [6]CHU Armand-Trousseau, PARIS, France, [7]University of Otago, OTAGO, New Zealand, [8]Guy's Hospital, London, United Kingdom.

Nager syndrome belongs to the acrofacial dysostoses group, which are characterized by the association of craniofacial and limb malformations. Recently, exome sequencing studies identified the *SF3B4* gene as the cause of this autosomal dominant condition in most patients. *SF3B4* encodes a highly conserved protein implicated in mRNA splicing and bone morphogenic protein (BMP) signaling. We performed *SF3B4* sequencing in 11 families (15 patients) suggestive of Nager syndrome and found 7 mutations predicted to result in haploinsufficiency. *SF3B4* is the major gene responsible for autosomal dominant Nager syndrome. All mutations reported were null mutations thus no genotype-phenotype correlation could be delineated. Mutation negative patients were phenotypically indistinguishable from mutated patients, thus genetic heterogeneity is likely.

Contribution of MSX1, PAX9, AXIN2 and WNT10A genes in four families with non syndromic tooth agenesis

N. Dinckan, *H. Kayserili, Z. Uyguner;*
istanbul medical faculty medical genetic department, istanbul, Turkey.

Tooth agenesis is the most common developmental abnormality of human dentition. Oligodontia is a subgroup of this developmental absence, where six or more permanent teeth are congenitally missing, excluding third molars. Oligodontia or hypodontia, both may occur as a single clinical entity or as a part of a syndrome. Investigations on model organisms and similarity analysis subjecting sequence/structure/functional relationships revealed more than hundreds of genes either directly or indirectly involved in the regulation of tooth development. Nevertheless, previously reported *MSX1*, *PAX9* and recently addressed *AXIN2* and *WNT10A* are the only genes currently associated with human non-syndromic tooth agenesis.

Four families,with isolated oligodontia are ascertained by detailed oral examination and panoramic radiographs. We aimed to investigate the role of *MSX1*, *PAX9*, *AXIN2* and *WNT10A* genes in the oligodontia in our cases, by sequencing the genes primarily only on index cases. If an alteration is identified, the concordance with oligodontia will be expanded to convey the point by analyzing other affected and unaffected individuals in the family.

PAX9 screening identified known heterozygous c.G718C in two of the families, one with further known heterozygous c.C119G, and other with further heterozygous novel c.-18G>A in *MSX1*, both segregating with oligodontia. Our investigation is continuing for screening of *AXIN2* and *WNT10A* genes.

We hope our findings will further delineate the contribution of *PAX9*, *MSX1*, *AXIN1* and *WNT10A* genes human tooth development during embryogenesis.

Copy number changes underlying syndromic and isolated bilateral radial ray aplasia: screening of a cohort of 20 probands

A. Jamsheer, *A. Sowinska, M. Socha, A. Latos-Bielenska;*
Department of Medical Genetics, University o Medical Sciences in Poznan, Poland, Poznan, Poland.

Radial ray aplasia is characterized by the absence of radial bone(s) often including thumb(s) and can either be isolated or syndromic. Although several causative genetic alterations resulting in radial ray aplasia have been identified, many patients have normal result of appropriate molecular screening. In this report we studied a cohort of 20 unrelated individuals affected by bilateral radial ray deficiency by means of conventional GTG-banding, MLPA for 1q21.1 locus, sequencing and MLPA for all exons of both TBX5 and SALL4, as well as array CGH. In six unrelated patients we found a microdeletion on 1q21.1, which was typical of TAR syndrome. Two probands carried point mutations in genes known to be involved in radial ray deficiency syndromes: one in TBX5, and the other in SALL4. Two additional probands had deletions encompassing either TBX5 or SALL4 detected upon MLPA and subsequently confirmed by array CGH. Finally, one additional case carried a pure terminal microduplication of 5q35.2-5q35.3 encompassing distal 5.4-5.6 Mb. To conclude, we detected copy number changes in nine patients, whereas a point mutation only in two out of the 20 probands from the initial

cohort. Although based on a small sample, our study shows that submicroscopic genomic rearrangements may account for a significant proportion of radial ray aplasia causative mutations. Therefore, we propose that either a combination of MLPA or qPCR for specific genes/loci or array CGH should be included into routine molecular screening of patients affected by syndromic or isolated radial ray deficiency.

Mutations in *COL2A1* cause a spectrum of clinically distinct conditions, including Stickler Syndrome, achondrogenesis and spondyloepimetaphyseal dysplasia (SEMD). SEMD is characterised by significantly short long bones, epi-metaphyseal irregularities and platyspondyly. The rare clinical variant, SEMD type Strudwick (OMIM reference 184250) is distinguished by congenital metaphyseal spurs and by early radiographic development of distinctive irregular 'dappled' metaphyses. Other features are chest deformities, secondary to rib involvement, cleft palate, laryngobronchomalacia, vitreoretinal anomalies and hearing loss. Previously only 10 individuals with six different *COL2A1* mutations have been described. Here eight new cases of SEMD type Strudwick are presented, the largest cohort to be reported so far. The clinical and radiological findings are described in detail to characterise the key manifestations further and highlight variability of this skeletal dysplasia condition. Analysis of the entire *COL2A1* gene revealed mutations in seven of these individuals. The majority of these are glycine missense mutations clustered together in a small number of exons in the triple helix domain, near similar mutations known to cause Kniest dysplasia and SEDC, though one mutation is located in exon 45. Mutations at glycine residues disrupt the tightly bound type II collagen helix, qualitatively affecting this key growth plate cartilage extracellular matrix protein, a molecular mechanism also of aetiological significance in a number of other conditions affecting fibrillar collagen. This increases to 13 the number of reported cases, expands the clinical spectrum of *COL2A1* mutations associated with SEMD type Strudwick and highlights the clinical utility of of characterising *COL2A1* mutations.

Shprintzen-Goldberg syndrome (SGS) is characterized by severe marfanoid habitus, intellectual disability, camptodactyly, facial dysmorphism and craniosynostosis. Recently, using family-based exome sequencing, we identified *SKI* as the gene responsible for SGS, with a cluster of mutations in exon 1 in 18 patients. Taking advantage of this work, we further clinically delineate SGS from the original cohort as well as new patients (mean age 20 years). All cases were sporadic except one family with somatic mosaicism and another following dominant inheritance. All mutations were found in exon 1, inframe. All patients display a remarkable phenotype associating a recognizable facial dysmorphism (scapho/dolichocephaly 94%, hypertelorism 89%, down slanting palpebral fissures 84%, malar hypoplasia 84%, proptosis 79%, micrognathia 79%) and severe skeletal manifestations (arachnodactyly 94%, feet malposition 89%, scoliosis 84%, pectus deformation 79%, joint contractures 79%, camptodactyly 47%). Craniosynostosis is not mandatory for the diagnosis (63%). Other common manifestations include hernia, loss of subcutaneous fat and myopia. The gene identification permitted to confirm the risk of aortic dilatation in affected patients (16% of the cohort, even in childhood), besides to the presence of valvular abnormalities (31%), justifying long-term regular cardiac follow-up from infancy. One young adult died suddenly without aortic dilatation, and another female died in her forties of respiratory insufficiency. Even if all genotyped cases reported to date had intellectual disabilities, we identified a case of SGS and a recurrent *SKI* mutation with normal intelligence but typical morphology, showing the importance of clinical delineation of a disease in light with molecular results.

Shprintzen-Goldberg syndrome (SGS) is a rare systemic connective tissue disorder characterized by craniofacial, cardiovascular, skeletal and skin manifestations that show significant overlap with Marfan (MFS) and Loeys-Dietz syndrome (LDS) features. A distinguishing finding in SGS patients is the presence of intellectual disability. Several lines of evidence confirm the key role of the transforming growth factor beta (TGFβ) signaling in the pathogenesis of MFS and LDS. Based on exome sequencing experiments and the hypothesis that the TGFβ pathway was highly likely to be involved in SGS, we identified de novo heterozygous mutations in the proto-oncogene SKI, a known repressor of TGFβ activity, in ten SGS patients. All mutations cluster in two distinct N-terminal regions of the protein: the SMAD2/3-binding domain and the Dachshund-homology domain (DHD) which mediates binding to SNW1 and N-Cor proteins, both essential for the transforming activity of SKI and for the recruitment of transcriptional corepressors.
Here we report on five additional de novo heterozygous missense SKI mutations in SGS patients, four recurrent and one novel. Adding our new findings to the existing data clearly reveals a pattern of hotspot mutations, with 48% (13/27) of the hitherto described mutations affecting the SKI-residues p.Gly34 and p.Pro35, both located in the SMAD2/3-binding domain. The importance of TGFβ in the SGS pathogenesis is further confirmed by enhanced activation of TGFβ signaling cascades and higher expression of TGFβ-responsive genes in cultured dermal fibroblasts from SGS patients.

Novel mutations in a family with spondylocostal dysostosis

C. Yang[1], *F. Tsai*[2], *Y. Chen*[1], *J. Wu*[1];
[1]*Academia Sinica, Taipei, Taiwan,* [2]*China Medical University Hospital, Taichung, Taiwan.*

Spondylocostal dysostosis (SCDO) comprises a heterogeneous group of vertebral malsegmentation disorders characterized by hemivertebrae, rib fusions and deletions. A SCDO family with two affected children inherited as an autosomal recessive mode was identified in Taiwan. Four known genes, DLL3, MESP2, LFNG, and HES7, causing autosomal recessive forms of SCDO were excluded to be disease-causing gene for this family by direct Sanger sequencing. Exome sequencing of this family using Illumina Hiseq2000 was subjected to identify novel homozygous and compound heterozygous variants. Four novel homozygous variants were identified and were not present in 376 Taiwanese controls. One of the variants is a homozygous insertion variant that results in a frameshift in amino acid sequence of a gene that has caused other disorders with vertebral malsegmentation and much severe clinical manifestations. Functional analysis revealed that the mutant protein presented different cytoplasmic pattern compared to the normal protein and may be functional inactive. This finding expends the phenotypic spectrum resulting from novel mutation of the gene.

Ift140/IFT140 mutations shown to cause *cauli* mouse phenotype and Jeune syndrome: a new biologic model for the study of ciliopathies

R. Savarirayan*, K. Miller, C. Ah-Cann, T. Tan, P. Farlie;*
Murdoch Childrens Research Institute, Melbourne, Australia.

Defects in cilia formation and function result in diverse ranges of human skeletal and visceral abnormalities, termed *ciliopathies*. As part of an ENU mouse mutation screen, we identified a mutant, *cauli*, with a phenotype consistent with an underling ciliopathy.
Mutant *cauli* embryos are characterized by mid-gestation lethality, craniofacial dysmorphism, neural tube defects, short, disorganised ribs, polydactyly, syndactyly, and internal organ defects. Linkage and candidate gene sequencing revealed homozygous mutations in the cilial gene, *Ift140,* as the cause of the *cauli* phenotype.
In mutant embryos; skeletal preparations revealed defects of the craniofacial skeleton, vertebrae, and thoracic rib cage; *in situ* hybridisation with *myogenin* showed disordered somite patterning, and with *Msx1* and *Sox9* abnormalities of the axial neural tube; and examination of primary cilia showed abnormal morphology, consistent with a defect of retrograde cilial transport. Components of the Shh/Grem1/Fgf signalling systems involved in limb development were also analysed by *in situ* hybridisation, showing consistent disruption of expression patterns between controls and *cauli* mutants.
The *cauli* phenotype is reminiscent of human short-rib polydactylies (SRP). Mutations in *IFT140* have also been shown to underlie a subset of patients with Jeune and Mainzer-Saldino syndromes. We screened patients with SRP phenotypes and found a novel, homozygous *IFT140* mutation in a patient diagnosed with Jeune syndrome.
These data confirm the utility of this mouse model to further understand the pleiotropic anomalies that arise in Jeune syndrome and other skeletal ciliopathies. It provides a platform for further analysis of the developmental signalling systems regulated via the primary cilium.

Deafness, myopia and slight bones changes caused by autosomal recessive mutations of COL9A3 gene: a new clinical entity?

F. Faletra[1], *A. P. D'adamo*[1], *I. Bruno*[1], *E. Athanasakis*[1], *S. Biskup*[2], *L. Esposito*[3], *P. Gasparini*[1];
[1]*Genetica Medica-Dipartimento Scienze e Riproduzione dello Sviluppo, Trieste, Italy,* [2]*CeGaT GmbH, Tübingen, Germany,* [3]*CBM S.c.r.l. Area Science Park, Trieste, Italy.*

Type IX collagen is expressed mainly in cartilage together with collagens II and XI. Collagen IX has been shown to be present also in the human intervertebral disc, vitreous humor, in the tectorial membrane of the inner ear. Also, there is temporal and spatial regulation of collagen IX gene expression, which seems to be more tightly regulated in cartilaginous than non-cartilaginous tissues. It is a heterotrimeric molecule formed by three genetically distinct chains: α1, α2, and α3 encoded by the COL9A1, COL9A2, and COL9A3 genes. Proteins are characterized by three collagenous (COL1, COL2, and COL3, numbered from the C terminus) that are joined by four small non-collagenous domains (NC1 to NC4). Although dominant and recessive mutations have been described in α1 and α2 chains, only heterozygous mutations of COL9A3 gene have been reported in human and related to: 1) multiple epiphyseal dysplasia 3, 2) susceptibility to an intervertebral disc disease, and 3) hearing loss. Here, we describe the first autosomal recessive family presenting with deafness, myopia and slight bones changes due to loss of functional mutations (c.1176_1198del, p.Gln393Cysfs*25) of COL9A3 gene. These findings further extend the knowledge of the role of type IX collagen in generating disease.

We observed a 16 year -old girl with features of Cri du Chat syndrome (CDC) connected with unusual changes of skeletal system due to unbalanced rearrangement der(5) t(5;7)(p13.3;p22.2). Interestingly epiphysial aseptic necrosis of the head of the second metatarsal bone well known as Freiberg's infraction (FI) were present in her mother and her grandmother, both carriers of t(5;7)(p13.3;p22.2). The mapping both chromosome breakpoints using RP11-666A5 and G248P8216C9 clones from 5p as well and RP11-261N10 and RP11-348A21 clones from 7p have been performed. We found that the breakpoint position mapped on 5p13.3 were in coding sequence of *ADAMTS12* gene and the breakpoint on 7p22.2 involved *SDK1* gene. Both genes probably were interrupted as a result of this rearrangement. Unknown genetic predisposition to occurrence of FI from one side and the observation of the cosegregation of FI together with t(5;7)(p13.3;p22.2) are suggestive as causal relationship with *ADAMTS12* gene disruption.

Fryns mesomelic dysplasia is caused by duplication of the HOXD cluster on chromosome 2q31

A. Toutain[1,2,3], *O. Pichon*[4], *A. Briand*[4], *B. de Courtivron*[5], *C. Bonnard*[5], *C. Le Caignec*[4];
[1]*Service de Génétique, Centre Hospitalo-universitaire, Tours, France,* [2]*Faculté de Médecine, Université François Rabelais, Tours, France,* [3]*INSERM U930, Tours, France,* [4]*Service de Génétique, Centre Hospitalo-universitaire, Nantes, France,* [5]*Service de Chirurgie Orthopédique Pédiatrique, Centre Hospitalo-universitaire, Tours, France.*

Mesomelic dysplasias are a heterogeneous group of inherited skeletal dysplasias among which Leri-Weill dyschondrosteosis caused by SHOX haploinsufficiency and its homozygous form, Langer dysplasia, are the most frequent and best known. Kantaputra type dysplasia is characterized by marked mesomelic shortening of the upper and lower limbs. A complex ~1 Mb genomic imbalance composed of two microduplications of 481 and 507 kb, separated by a segment of normal copy number, on chromosome 2 (2q31.1-q31.2) has been identified in the original Thai family described by Kantaputra et al.
In 2011, at the ESHG meeting we reported a female patient and her similarly affected father who had the same phenotype as a family published in 1988 by Fryns et *al.* In both families the patients had severe bilateral shortening and bowing of the forearms with ulnar deviation of the hands resulting from severe developmental abnormality of the ulna, without any other features particularly with no lower limbs involvement. A 60K oligoarray CGH performed in our patient identified in the 2q31.1 region a 200 Kb microduplication which was confirmed by qPCR. No other imbalance was identified. The genomic rearrangement resulted in the duplication of the entire

HOXD cluster and of the neighbouring gene EVX2. Parental analysis showed that it was present in her affected father. Molecular karyotyping was: arr 2q31.1(176,883,603-177,090,474)x3 pat (hg19). Our results confirm that duplication to the entire HOXD cluster leads to mesomelic dysplasia and significantly reduce the minimum size of the duplication responsible for this phenotype.

[1]Foetopathologie, CHU, BORDEAUX, France, [2]Anatomie Pathologique, Troyes, France, [3]Foetopathologie, CHI, CRETEIL, France, [4]Foetopathologie, CHU, CAEN, France, [5]Foetopathologie, CHU, NANTES, France, [6]Foetopathologie, CHU, BREST, France, [7]Foetopathologie, CHU, LYON, France, [8]Foetopathologie, CHU, LILLE, France, [9]Société Française de Foetopathologie, Rennes, France, [10]Service de Génétique CHU, REIMS, France.

Hypophosphatasia (HP) is a rare inherited disorder characterized by bone defective mineralization, caused by mutations within the gene that encodes the tissue-nonspecific enzyme of alkaline phosphatase (TNSALP). Two of the 6 recognized forms can be detected by prenatal ultrasounds, showing poor skeletal mineralization and fetal crowding. If most prenatal forms are lethal (LP-HP), a few benign forms are reported with a third trimester and a postnatal improvement (BP-HP).
Sixteen fetal cases of P-HP were collected from members of the Société Française de Foetopathlogie (SoFFoet) between 1983 and 2012 in order to precise the fetal phenotype. This retrospective study included X-Rays, fetal examination and TNSALP mutations.
Termination of pregnancy was made after molecular prenatal diagnosis in 2 cases at 15 and 16 weeks of gestation (WG), and after prenatal ultrasounds in 13 cases between 15 and 33 WG. One fetus was dead in utero at 35 WG. Dysmorphy was reported in 10/16 cases. The skull was soft on the touch with absence of ossification on X-Ray in any case. Micromelia and short bowing legs were present in all the fetus except one. Spurs were present in 9/16 cases. The 16 fetuses showed a severe hypomineralization without any fracture. Absence ossification was constant but heterogeneous along the vertebral column and the extremities. The metaphyses appeared bifid with a thickened hypertrophic cartilage on microscopic sections. X The fetus were composite heterozygous in 10/16 genetic studies with different family genotypes.
The 2 forms of LP-HP and BP-HP will be discussed in this retrospective study.

Three generation family with kyphomelic dysplasia suggests autosomal dominant inheritance

O. M. Vanakker[1], *U. I. Fränkel*[2], *A. De Paepe*[1];

[1]Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium, [2]Department of Paediatrics, Zorgsaam Hospital, Terneuzen, Netherlands.

Kyphomelic dysplasia (KD) is a rare skeletal dysplasia belonging to the group of bent bone dysplasias. It represents a heterogenous group of disorders, with at least three distinct entities: Schwartz-Jampel syndrome (SJS), Cartilage Hair Hypoplasia (CHH) and 'true' KD. For the latter, the genetic background is unknown and autosomal recessive inheritance is presumed based on several sporadic cases with parental consanguinity.
We report a three generation family presenting with a true KD phenotype. The proband was born at term after an uneventful pregnancy. Her length and weight at birth were 37cm and 1578g respectively. She had severe rhizomelic shortening of upper and lower limbs. Radiographs showed stubby femora which were extremely curved. Iliac wings were short and widened; the humeri were also short and dumbbell-shaped.
The mother of the proband has a similar disproportionate short stature phenotype. Radiographs taken at birth revealed severe femoral bowing, though less prominent compared to her daughter. Follow-up radiographies in the mother demonstrated gradual improvement of the bowing over several years. The maternal grandfather of the proband had an identical phenotype. All had a normal neuromotor development. There were no signs of myotonia or ocular problems (SJS) nor evidence for immunodeficiencies or anaemia (CHH).
This family with true KD is to our knowledge the first to demonstrate that at least a subtype of KD has an autosomal dominant mode of inheritance. This observation has important consequences for genetic counselling of patients with KD, and identification of other families may allow clarification of the genetic background.

Identification of new SQSTM1 mutations in familiar Paget's disease

R. Usategui Martin[1], *M. López Bartolomé*[2], *E. Bueno Martínez*[1], *J. Del Pino Montes*[2], *R. González Sarmiento*[1];

[1]Unidad de Medicina Molecular, Dpto.de Medicina, IBSAL-CIC, Universidad de Salamanca-CSIC, Salamanca, Spain, [2]Servicio de Reumatología, Hospital Clínico Universitario de Salamanca (IBSAL), Salamanca, Spain.

Paget's disease of bone (PDB) is a focal disorder of bone that affects segmentally the skeleton, presenting a increase in osteoclast number, size and activity that results in a variegated and anarchic bone structure that alters the mechanical properties.
There is a tendency to familial aggregation (15-40%) with an autosomal dominant pattern modified by environmental factors. The most plausible candidate gene is sequestosoma1 gene, encoding the p62 protein, which plays an important role in cellular signal crossroads related with osteoclastogesis such as NF-kB pathway.
We studied in 21 families with proven diagnosis of PDB, exons 6, 7 and 8 of SQSTM1 gene in genomic DNA by PCR and subsequent automatic sequencing Big DyeTerminators.
Our results show that 8 of the 21 families studied (38.09%) were carriers of a mutation in the SQSTM1 gene. Three of the eight families carry the mutation p.P392L (12.5% of all patients studied), often described in the literature. In three families appears the p.E273D mutation and in other appears the p.R321C mutation neither described in the literature.
"In silico" study categorizes both novel mutatations as pathogenic. A population study in 100 healthy individuals alleles by dHPLC (Denaturing High Pressure Liquid Chromatography), failed to detect the mutations.
We report two new Spanish families carrying novel mutations in SQSTM1 gene which reinforce the role of this gene in Paget disease.

The role of matrix metalloproteinases (MMP2, MMP9 and MMP12) gene polymorphisms in abdominal aortic aneurysm and aortoiliac occlusive disease

A. Korcz[1], *S. Hryhorowicz*[2], *J. Mikolajczyk-Stecyna*[1], *K. Pawlaczyk*[3], *M. Zowczak-Drabarczyk*[3], *M. Molinska-Glura*[3], *G. Oszkinis*[3], *R. Slomski*[1], *M. Gabriel*[3];

[1]Polish Academy of Sciences, Poznan, Poland, [2]Adam Mickiewicz University, Poznan, Poland, [3]Poznan University of Medical Sciences, Poznan, Poland.

Abdominal aortic aneurysm (AAA) and aortoiliac occlusive disease (AIOD) are common vascular disorders considered to be complex diseases with both genetic and environmental risk factors involved. Destructive remodeling of extracellular matrix and histological signs of chronic inflammation associates both of these pathologies. Matrix metalloproteinases play a major role in the remodeling of the extracellular matrix of aorta, and their contribution to the pathogenesis of AAA is unquestionable. The purpose of this study was to examine the role of MMP2(nt-1306); MMP9(nt-1562); MMP12 (nt-82) gene polymorphisms in the development of AAA or AIOD in Polish patients. The case-control designed study included three selected groups: 308 patients with AAA and 312 patients with AIOD who underwent surgery; 375 individuals from control group free of these vascular diseases. Genotypes were compared with demographic and clinical data of subjects and analyzed in relation to risk factors. We found significant differences between patients with AAA and control group for MMP9 (nt-1562) (p=0,026) and MMP12 (nt-82) (p=0,037) gene polymorphisms. There were also significant differences between patients with AIOD and control group for MMP9 (nt-1562) (p=0,014). No differences were found in case of MMP2 (nt-1306) gene polymorphism. In a multivariable logistic regression analysis adjusted for traditional cardiovascular risk factors MMP12 was an independent risk factor for AAA and MMP9 for AIOD. In conclusion, we suggest that polymorphism in MMP12 may independently contribute to pathogenesis of AAA whereas MMP9 polymorphism is a risk factor of AIOD. Supported by Natio-

Genetic variants in selenoprotein genes SEPP1, TXNRD1, TXNRD2 and abdominal aortic aneurysms development

E. Strauss[1], *R. Staniszewski*[2], *G. Oszkinis*[2];
[1]*Institute of Human Genetics the Polish Academy of Sciences, Poznan, Poland,*
[2]*Department of General and Vascular Surgery, Poznan University of Medical Sciences, Poznan, Poland.*

Enhanced oxidative stress in cardiac and vascular myocytes is causative to cardiovascular diseases. Selenium, a trace element, as a component of selenoproteins helps control the intracellular redox state. In the presented study the associations between the four SNPs in genes encoding selenoproteines: selenoprotein P (SEPP1 rs7579G>A, rs3877899G>A), thioredoxin reductase 1 (TXNRD1 rs35009941C>G) and 2 (TXNRD2 rs9605031C>T) and the abdominal aortic aneurysm (AAA) occurrence were examined.
The case-control study encompassed a series of 506 AAA patients and 468 controls. In patients the presence of symptomatic peripheral arterial disease (PAD) was determined. High-throughput SNPs genotyping was performed using the TaqMan pre-designed assays. Associations between alleles/haplotypes and the intermediate traits related to the vascular diseases were also examined.
SEPP1 SNPs were in complete linkage disequilibrium, then only three of rs7579-rs3877899 haplotypes: G-G (0.469), A-G (0.293), G-A (0.238) were observed. None of the studied alleles/haplotypes was associated with AAA. However, the higher frequency of the SEPP1 rs3877899A allele (the G-A haplotype) carriers in AAA subjects with advanced PAD (53.5%) as compared to those without PAD (30.9%, p=0.012) and controls (41.7%, p=0.1) were noted. The association between the SEPP1 rs7579A allele (the A-G haplotype) and obesity in AAAs was also found (p<0.005), but no significant relations between studied variants and age, gender, hypertension, diabetes and HDLC level were noted.
In conclusion, selenoprotein P gene haplotypes are associated with the development of peripheral atherosclerosis and with obesity in abdominal aortic aneurysms. The work was supported by the National Science Centre in Poland under grant No. NN403250440.

The IL23R Non-Synonymous Polymorphism rs11209026 is Associated with Radiographic Sacroiliitis in Spondyloarthritis

F. Costantino[1], *A. Kadi*[1], *B. Izac*[1], *A. Leboime*[2], *R. Said-Nahal*[2], *H. Garchon*[1,2,3], *G. Chiocchia*[1], *M. Breban*[1,2,3];
[1]*Institut Cochin, Paris, France,* [2]*Hôpital Ambroise Paré, Boulogne-Billancourt, France,* [3]*Versailles-Saint Quentin University, Versailles-Saint Quentin, France.*

Objective: Spondyloarthritis (SpA) is a group of inflammatory articular disorders sharing genetic background. The non-synonymous single-nucleotide polymorphism rs11209026 (Arg381Gln) in the IL23R gene, has reproducibly been shown as associated with ankylosing spondylitis (AS). Here, we examined the association between rs11209026 and SpA as a whole. Particular attention was devoted to genotype-phenotype correlation.
Methods: rs11209026 was genotyped in a French collection of 415 cases/372 controls and 383 trios. Association analysis was carried out in SpA as a whole group and then separately in AS and non-radiographic SpA (non-AS) patients. Phenotype/genotype correlations were examined using a logistic regression analysis.
Results: A significant association between rs11209026 and SpA was only identified in the familial dataset (P = 0.03; OR = 0.57). Strong association with AS was observed in both case/control and familial datasets (P = 4.5x10-4 and 4x10-3, respectively). In contrast, such association was not detected with the non-AS group. Furthermore, rs11209026 frequency was significantly different between the AS and non-AS patients (P = 2.5x10-3). Phenotype/genotype correlation study revealed that both radiographic sacroiliitis and an early onset were independently associated with a lower frequency of the rare protective rs11209026 allele A in patients (P = 9x10-3 and 8x10-3, respectively).
Conclusion: Our study replicated the robust association between rs11209026 and AS, in the French population. However such association was restricted to AS patients, as compared to non-radiographic SpA. The fact that it was independently conditioned by radiographic sacroiliitis and age at onset suggests that rs11209026 could affect the disease severity rather than susceptibility.

Transcriptomic Analysis Of Derived Dendritic Cells (MD-DCs) Reveals Several Genes Differentially Regulated Between Spondyloarthritis (SpA) Patients And Healthy Controls

A. Talpin[1], *N. Bonilla*[1], *F. Costantino*[1], *A. Leboime*[2], *F. Letourneur*[1], *S. Jacques*[1], *F. Dumont*[1], *H. Garchon*[1,2,3], *M. Breban*[1,2,3], *G. Chiocchia*[1];
[1]*Institut Cochin, Paris, France,* [2]*Hôpital Ambroise Paré, Boulogne-Billancourt, France,* [3]*Versailles-Saint Quentin University, Versailles-Saint Quentin, France.*

Introduction: As originally shown in an HLA-B27 transgenic rat model, monocytes-derived DCs from SpA patients exhibit a weaker stimulatory efficiency of CD4+ T cells than control DCs.
Aim: To identify genes differentially expressed in MD-DCs from SpA patients, as compared to healthy controls.
Materials and Methods: Monocytes were purified from 9 HLA-B27+ SpA patients and 10 controls PBMCs using anti-CD14-coupled immunomagnetic beads and cells were further cultured with IL-4 and GM-CSF for 7 days. MD-DCs were then stimulated with LPS for 6 and 24 hours. Transcriptomic study was performed with Affymetrix HuGene 1.0 ST microarrays on unstimulated and stimulated MD-DCs. Gene expression levels in patients and controls were compared using a multivariate design under a linear model. Real-time quantitative PCR (RT-PCR) was performed for genes validation.
Results: Transcriptomic analysis revealed 104 genes differentially expressed in MD-DCs from SpA patients compared with controls (p<0.01 and fold-change ±1.5). Five candidate genes have been validated by RT-PCR (ADAMTS15, F13A1, SELL, ERAP1 and CITED2). Interestingly, expression of ADAMTS15, belonging to the metallopeptidase family, was inversely correlated with the expression of the transcription factor CITED2 (R=0.75, p=0.0003). Further, in silico pathway analysis conducted on CITED2 co-expressed genes provided identification of the Wnt signaling pathway.
Discussion: This transcriptomic study reveals striking differences in the gene expression patterns of SpA MD-DCs compared to controls. Up-regulation of ADAMTS15 highlights the potential role of metallopeptidase in SpA pathogeny. Moreover, deregulation in SpA patients of the Wnt signaling pathway may have consequences on the balance between osteoblast and osteoclast functions.

Novel homozygous missense mutations in the SLC2A10 gene in a Turkish pediatric patient with arterial tortuosity syndrome.

S. G. TEMEL[1], *O. BOSTAN*[2], *D. PROOST*[3], *L. VAN LAER*[3], *E. CIL*[2], *B. LOEYS*[3];
[1]*University of Uludag, Faculty of Medicine, Department of Histology & Embryology, Near East University, Faculty of Medicine, Department of Histology & Embryology, Bursa, Mersin, Turkey,* [2]*University of Uludag, Faculty of Medicine, Department of Pediatric Cardiology, Bursa, Turkey,* [3]*Center for Medical Genetics, Antwerp University Hospital and University of Antwerp, Antwerp, Belgium.*

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive connective tissue disorder, mainly characterized by tortuosity and elongation of the large- and medium-sized arteries with predisposition to stenoses and aneurysms. ATS is caused by mutations in the SLC2A10 gene, encoding for the facilitative glucose transporter 10 (GLUT10) and is described typically in pediatric patients. We report a 2 years old boy with ATS who initially presented with a cardiac murmur. Echocardiography at the age of one month demonstrated dilatation of the aortic root (15mm) and tortousity in the descending aorta. The main clinical findings included elongated face, saggy cheeks, micrognathia, malar hypoplasia, joint hypermobility and hyperextensible skin. Follow-up echocardiography showed an increase of the diameter of the aortic root to 32mm and 35 mm at the age of 8 months and 2 years old, respectively. Angiography and computerized tomography angiography showed fusiform aneurysmatic dilatation of ascending aorta, marked tortuosity of both pulmonary arteries and thoracic aorta, stenosis in vena cava inferior and collateral structure associated with right hepatic vein. Sequencing of the SLC2A10 gene in the proband revealed the presence of a novel pathogenic homozygous missense variant (c.727C>A). Heterozygous SLC2A10 mutations were shown in her mother and father, demonstrating true homozygosity. The pathogenic variant leads to a p.Gln243Lys change

in the seventh transmembrane domain of GLUT10. The proband underwent aortic root replacement surgery. ATS resembles Loeys-Dietz and Marfan related disorders, so timely differential diagnosis is extremely important for early diagnosis and intervention of aneurysms to prevent serious vascular complications.

SLC2A10 knockdown in aortic smooth muscle cells underscores mitochondrial dysfunction as a key pathogenetic event in arterial tortuosity syndrome

A. Willaert, *A. Boel, W. Trypsteen, A. Fieuw, B. Menten, B. Callewaert, A. De Paepe, P. Coucke;*
Ghent University Hospital, Ghent, Belgium.

Arterial tortuosity syndrome (ATS) is a recessively inherited connective tissue disorder, mainly characterized by tortuosity, stenosis and aneurysm formation of the main arteries. In patient tissue samples, fragmentation of elastic fibers and enhanced TGFβ-signaling was found. ATS is caused by loss-of-function mutations in the *SLC2A10* gene, encoding the facilitative glucose transporter GLUT10. The function of this transporter and the pathogenesis underlying ATS has been a matter of debate. Cellular studies and a recent ATS zebrafish model suggested a role for GLUT10 as a mitochondrial transporter of the antioxidant dehydroascorbic acid (vitamin C). GLUT10 loss-of-function would therefore lead to increased oxidative stress and mitochondrial dysfunction associated with disturbed TGFβ-signaling. In this study we wanted to investigate the initial alterations in gene expression following *SCL2A10* knockdown in human aortic vascular smooth muscle cells (aVSMC). Two different siRNA's, targeting *SLC2A10*, were separately transfected in aVSMC, both resulting in knockdown efficiencies of >80%. RNA was extracted at 24 hours post-transfection and loaded on Agilent 8X60k expression arrays. Differential gene expression was determined as transcript-level changes of ≥1.5 ($p<0.05$) relative to control samples. As a result, 264 different genes and 7 lincRNA's showed differential expression in both siRNA treatments. In-depth data mining indicates disturbed mitochondrial functioning, elevated mitochondria-mediated apoptosis, altered TGFβ-signaling and disturbed production of extracellular matrix components. However, at the cellular level, no apoptosis or pronounced disruption of mitochondrial integrity was detected at this early stage after knockdown. Altogether, these data further evidence a key role for proper mitochondrial functioning in vascular development.

Influence of promoter SNPs on the ABCG1 transporter gene expression level

V. Miroshnikova[1,2], *E. Demina*[1], *N. Mayorov*[2], *V. Davydenko*[2], *P. Kurjanov*[2], *V. Vavilov*[2], *A. Denisenko*[3], *A. Schwarzman*[1];
[1]*Petersburg nuclear physics institute, Gatchina, Russian Federation,* [2]*Saint-Retersburg Pavlov State Medical University, Saint-Retersburg, Russian Federation,* [3]*Saint-Petersburg institute of experimental medicine, Saint-Petersburg, Russian Federation.*

Atherosclerosis is characterized by cholesterol deposition in vascular wall. Transporter ABCG1 mediates cholesterol efflux from macrophage foam cells to high density lipoproteins. However the importance of ABCG1 gene expression in human macrophages for atherosclerosis development is still undiscovered. Two SNPs -134T/G (rs1378577) and -204A/C (rs1893590), which can affect ABCG1 gene expression level, were identified in promoter region of ABCG1 gene. The aim of this study was to investigate influence of SNPs -134T/G and -204A/C on ABCG1 gene expression level and association of ABCG1 gene expression in monocytes and macrophages with atherosclerosis. Human peripheral blood monocytes were obtained from 26 patients with angiographically proved atherosclerosis and 20 healthy individuals. To get monocyte-derived macrophages for 11 persons of each group, monocytes were cultured with macrophage colony-stimulating factor (M-CSF) for 5 days. ABCG1 mRNA levels were measured using real time PCR. For identification of -134(T/G) and -204(A/C) genotypes allele-specific PCR and PCR with restriction analysis, respectively, were used. Macrophage ABCG1 mRNA levels were significantly reduced in group of patients when compared with the controls: average levels were 1.33±0.48 and 2.46±0.45 ($p<0.001$). There were no differences in monocyte ABCG1 mRNA levels between patients and controls. And there was no correlation between -134(T/G) and -204(A/C) SNPs and ABCG1 mRNA levels in monocytes and macrophages. These results suggest that reduction of ABCG1 expression in macrophages is associated with atherosclerosis, but ABCG1 genetic variants -134(T/G) and -204(A/C) do not affect this expression.

Cartilage-hair-hypoplasia is a rare autosomal recessive metaphyseal dysplasia due to RMRP (the RNA component of the RNase MRP -ribonuclease mitochondrial RNA processing- complex) gene mutations. So far, more than 90 mutations have been reported in the promoter and the transcribed regions. Clinical characteristics include short-limbed short stature, sparse hair and defective cell-mediated immunity. We report herein the antenatal presentation of a female fetus, in whom CHH was suspected from 23 weeks' gestation, leading to a medical termination of the pregnancy at 34 weeks'gestation, and thereafter confirmed by morphological and molecular studies. Post-mortem examination confirmed short stature and limbs, and revealed thymic hypoplasia associated with severe CD4 T-cell immunodeficiency along with extensive non caseating epithelioid granulomas in almost all organs, which to our knowledge has been described only in five cases. Molecular studies evidenced on one allele the most frequently reported founder mutation NR_003051: g.70A>G, which is present in 92% of Finnish patients with Cartilage Hair Hypoplasia. On the second allele, a novel mutation consisting of a 10 nucleotide insertion at position -18 of the promoter region of the RMRP gene (M29916.1:g.726_727insCTCACTACTC) was detected. The founder mutation was inherited from the father, and the novel mutation from the mother. To our knowledge, this case report represents the first detailed fetal analysis described in the literature.

Expanding the phenotypic and mutational spectrum of EDS dermatosparaxis type: a report of five new patients

T. Van Damme[1], *F. Malfait*[1], *S. Symoens*[1], *Y. Alanay*[2], *C. Giunta*[3], *U. Lindert*[3], *M. Rohrbach*[3], *S. Pelin Ozlem*[4], *A. Colige*[5], *A. De Paepe*[1];
[1]*Center for Medical Genetics, Ghent University, Ghent, Belgium,* [2]*Pediatrics Genetics, Department of Pediatrics, Acibadem University School of Medicine, Istanbul, Turkey,* [3]*Division of Metabolism, University Children's Hospital, Zurich, Switzerland,* [4]*Ihsan Dogramaci Children's Hospital, Clinical Genetics Unit, Hacettepe University, Ankara, Turkey,* [5]*Laboratory of Connective Tissues Biology, University of Liège, Liège, Belgium.*

Ehlers-Danlos Syndrome (EDS) dermatosparaxis type is a recessively inherited connective tissue disorder, caused by deficient activity of ADAMTS2, which cleaves the amino (N)-propeptide of type I procollagen. Only ten human EDS dermatosparaxis patients have been reported, in six of whom a homozygous p.(Q225*) was identified. Due to the decreased N-proteinase activity, uncleaved pN-collagen molecules are incorporated in the collagen fibrils, resulting in fibrils with a pathognomonic 'hieroglyphic' appearance. All reported patients present a recognizable phenotype with a characteristic dysmorphic facies, extreme skin fragility and -laxity, excessive bruising and sometimes internal complications.
We report clinical, molecular, biochemichal and ultrastructural findings in five new EDS dermatosparaxis patients from four independent families. Three patients display a strikingly milder phenotype than that of previously reported patients, mainly with regard to skin fragility and -laxity and dysmorphic features. Molecular ADAMTS2 analysis revealed three novel homozygous loss-of-function mutations (c.2927_2928delC (p.(P976Rfs*42)), c.669-670dupG (p.Pro224Alafs*41), c.2751-2A>T) and a compound heterozygous mutation (c.2T>C (p.(Met1Thr)) and c.888-891delTGAA (p.(M295Nfs25*))).
SDS-PAGE showed accumulation of bands representing pN alpha chains and decrease of bands representing mature alpha chains of type I procollagen in all patients. Ultrastructural dermal analysis revealed milder collagen fibril

abnormalities than those of previously reported patients. Collagen fibrils showed irregular contours and a somewhat branched appearance, but their general cylindrical appearance was preserved. These observations suggest incomplete N-propeptide cleavage, either due to residual enzyme activity or compensating enzymes.
Together our findings show that milder forms of EDS dermatosparaxis type exist, which may remain undiagnosed (in a non-specialised clinical setting).

P01.074

Marked intrafamilial variation in Ehlers-Danlos Syndrome type IV is explained by biallelic *COL3A1* mutations.

A. Jørgensen[1], *T. Fagerheim*[1], *S. Rand-Hendriksen*[2], *M. Pepin*[3], *P. Lunde*[4], *D. F. Leistritz*[3], *U. Schwarze*[3], *P. H. Byers*[3,5];
[1]*Medical Genetics Department, Division of Child and Adolescent Health, University Hospital of North-Norway, Tromsø, Norway,* [2]*TRS, National Resource Centre for Rare Disorders, Sunnaas Rehabilitation Hospital, Nesoddtangen, Norway,* [3]*Department of Pathology, University of Washington, Seattle, WA, United States,* [4]*Division of Cardiothoracic and Respiratory Medicine, University Hospital of North-Norway, Tromsø, Norway,* [5]*Department of Medicine, University of Washington, Seattle, WA, United States.*

Ehlers-Danlos syndrome (EDS) type IV, the vascular type, is an autosomal dominant disorder caused by mutations in *COL3A1*,which encodes the chains of type III procollagen. We identified a family in which there was marked clinical variation with the earliest death due to extensive aortic dissection at age 15 years and other family members in their 80s with no complications. The proband was born with right sided clubfoot but was otherwise healthy until he died unexpectedly at 15 years. He and his sister each had two *COL3A1* mutations (c.1786C>T, p.Arg596Ter, in exon 26 and c.3851G>A, p.Gly1284Glu, in exon 50). The mutations segregated to different alleles. In mRNA in cells from the sister the missense mutation in exon 50 was apparently „homozygous", consistent with nonsense mediated instability of the mRNA that carried the premature termination codon. Cells from the compound heterozygote produced a reduced amount of type III procollagen that was largely retained in the cells, the chains of which all had abnormal electrophoretic mobility. Cells from an individual heterozygous for the missense mutation produced some normal and some abnormal type III procollagen. Cells from an individual heterozygous for the nonsense mutation produced a reduced amount of apparently normal type III procollagen. This is only the second instance of compound heterozygosity for deleterious *COL3A1* mutations and in both instances the individuals with bi-allelic mutations have a significantly worse outcome than the heterozygotes. This is a rare explanation for marked clinical variation in individuals with mutations in *COL3A1*.

Dermal electron microscopy findings in the Ehlers-Danlos Syndromes (EDS).

N. Stembridge[1], ***A. M. Vandersteen***[1], *N. Ghali*[1], *R. Pollitt*[2], *M. Nesbitt*[3], *P. Sawle*[1], *D. Ferguson*[4], *F. M. Pope*[1];
[1]*UK National EDS Clinic, Harrow, United Kingdom,* [2]*Sheffield Children's NHS Foundation Trust, Sheffield., United Kingdom,* [3]*Sheffield Children's NHS Foundation Trust, Sheffield, United Kingdom,* [4]*Nuffield Department of Clinical Laboratory Science, University of Oxford, John Radcliffe Hospital, Oxford, United Kingdom.*

There is limited published data describing dermal collagen ultrastructure (Electron Microscopy, EM) across EDS subtypes. We present data from 188 patients, correlated with clinical, molecular and biochemical findings.
We identified normal collagen fibril size in the majority of patients classified as hypermobile EDS (64.6% [n=82]), as well as other patients with arterial aneurysm and dissection and non-specific features of hereditary disorders of connective tissue.
Fibril size irregularity is seen in the majority of patients with confirmed vascular EDS (vEDS) (90% [n= 10]), but also in patients with confirmed collagen (I) and (V) abnormalities, and rarely in other patients with EDS III/BHS. We could not confirm the findings of Ong et al (2012) of abnormal fibroblast shape, lysosomal inclusions, dermo-epidermal junction abnormalities in 10 confirmed vEDS patients.
Occasional small collagen flowers were common in EDS III/BHS (30.7% [n=39]), but also seen across all EDS subtypes. Dilated endoplasmic reticulum, collagen fibril kinking and loose or dense packing were seen across all EDS subtypes and were non-specific findings. Numerous (>5%) collagen cauliflower fibrils were specific to the EDS classical subtype, however we did not identify Collagen (V) or (I) mutations in all of these patients (25% [n=3]).
No EM finding was completely sensitive or specific to a particular EDS subtype. Detailed clinical, genetic, biochemical and structural assessment remains the gold standard for assessment of these patients. There is limited data describing dermal collagen fibril characteristics and fibroblast architecture and dimensions in the normal population.

P01.076

A second family carrying a mutation of the PLOD3 identified by whole exome sequencing: a new subtype of EDS?

E. Steichen-Gersdorf[1], *S. Kircher*[2], *M. Hagl*[2], *J. Behunova*[2], *O. Brandau*[2], ***F. Laccone***[2];
[1]*Univ. Klinik f. Kinder- und Jugendheilkunde, Innsbruck, Austria,* [2]*Institute of Medical Genetics, Vienna, Austria.*

A male patient aged 10 years was referred with severe S-formed scoliosis, ptosis of the right eyelid, asymmetrical face, midface hypoplasia and shallow orbitae with pseudoexophtalmus. Additionally, bilateral adducted thumbs, non progressive flexion contractures of proximal finger joints, atrophy of thenar muscles and overall poor muscle development were noted. Bilateral sensorineural deafness was diagnosed at the age of two years. He has a thin and soft skin, without scarring, and reduced skin creases on both palms. Motor development was slightly retarded and cognitive function mildly impaired. The patient's sister was similarly affected, but without significant scoliosis. Parents were healthy, non-consanguineous, but originating from an isolated rural region. A so far uncharacterized "complicated form" of Ehlers-Danlos-syndrome was suspected. We performed whole exome sequencing, analyzed the data under the hypothesis of parental consanguinity and identified the Lysyl hydroxylase3 gene (PLOD3) involved in the posttranslational modification of collagen biosynthesis as a strong candidate gene. Both patients were homozygous for the c.1935+1G>A mutation and both parents were carriers. Study of the literature unveiled one single family carrying a mutation in this gene with a strikingly similar phenotype (Salo et al., 2008 Am J Hum Genet 83:495, OMIM: #612394), which suggests a syndromic pattern caused by PLOD3-mutations. Therefore the PLOD3 caused disease may be considered a new form of the vascular-contractural-deafness type of EDS, expanding the group of diseases caused by a dysfunction of the collagen assembly.

P01.077

Development of sporadic dilatative pathology of ascending thoracic aorta (DPATA): impact of Fibrillin-1(FBN1) polymorphysms (rs1036477, rs10519177, rs755251, and rs2118181)

G. Jariene, *R. Sepetiene, G. Zukovas, E. Juskaite, Z. Stanioniene, R. Benetis, V. Lesauskaite; Institute of Cardiology, Kaunas, Lithuania.*

Dilatation of ascending thoracic aorta in patients with Marfan syndrome is caused by *FBN1* mutations. The role of *FBN1* polymorphisms within sporadic cases of DPATA is less explored.
The aim of our study - to investigate the association of *FBN1* gene *SNPs* (*rs1036477, rs10519177, rs755251* and *rs2118181)* within development of different phenotypes (post-stenotic aortic dilatation (PSAD); aneurysm of thoracic aorta (ATA); and dissection of thoracic aorta (DTA) of sporadic DPATA.
Methods. Study included **238** patients who were undergoing aortic reconstruction due to DPTA at the Department of Cardiovascular Surgery, Lithuanian University of Health Sciences. No patients had phenotypic characteristic of Marfan syndrome. Reference group (**n=445**) was formed from a random sample of Kaunas population. Both groups age and sex matched. DNA was extracted from blood, concentration was measured by spectrophotometry. *FBN1 SNPs* (*rs1036477* and *rs2118181, rs10519177, rs755251)* were analysed by real-time PCR. Results were calculated statistically by approved Fisher's exact test, logistic regression.
Results: The patients with DTA had a significantly higher frequency of *FBN1* G/G genotype than the reference group subjects.

Table 1

FBN1 GG genotype frequency	DTA n=52	PSAD n=66	ATA n=120	Reference group n=445
rs2118181	8.51% *	3.17%	2.63%	1.35%
rs1036477	8.51% *	3.17%	2.63%	1.35%
rs10519177	17.02% *	7.81%	12.39%	6.97%
rs755251	17.02% *	7.81%	12.39%	6.97%

*p<0.05

It was associated with increased odds of DTA (*rs2118181, rs1036477* OR=6.8; 95 % CI 1.849-25.058, p=0.004; rs10519177, rs755251 OR=2.7; 95% CI 1.178-6.369, p=0.019).

Summary. Our data draw attention to the pathogenetic link between sporadic DTA and aortic pathology in Marfan syndrome.

P01.078

Assessment of the enrichment for rare coding variants in 16 cases of familial fibromuscular dysplasia

*R. Kiando[1,2], P. Plouin[2,3], X. Jeunemaitre[1,2,3], **N. Bouatia-Naji**[1,2];*
[1]INSERM UMR970 Paris Cardiovascular Research Center (PARCC), Paris, France, [2]Paris Descartes University, Paris Cité Sorbonne, Paris, France, [3]AP-HP Centre for Rare Vascular Diseases, Hopital Européen Georges Pompidou, Paris, France.

Fibromuscular dysplasia (FMD) is an arterial disease characterized by non-atherosclerotic stenoses reported in renal (70%) and extra-cranial carotid (30%) arteries. FMD predisposes to hypertension, renal ischemia and stroke. The causes of FMD are unknown and it occurs predominantly in females (age<50 years) with a prevalence of ~4/1000. Despite evidence for its inheritance the genetics of FMD is under-investigated. The aim of this study is to assess the role of rare coding and putatively functional variants in the onset of familial FMD.

Patients are five affected sib-pairs and two sib-trios (N=16; mean age=51yrs, min=32; max=61) with confirmed multifocal "string-of-beads" FMD diagnosed by angiography/scanner. Mean age diagnosis =44yrs (min=23; max=57). Exome sequencing and variant calling was performed by IntegraGen® using Agilent's capture Kit (V4) and Hiseq2000 (Illumina®).

We identified 4,311 confident (high calling-score and depth >8X) missense rare (MAF<0.02 in EVS and/or 1000G) variants predicted to be damaging (PolyPhen2) in 3,414 genes. We performed a genomic burden test for highly mutated genes (>= 4 variants, N=45) and used the EVS data from ~4,300 unselected Europeans as controls. Fischer exact test revealed two genes significantly enriched for putatively causative variants at the genomic level (P=4.9x10^{-8} and P=7.1x10^{-7}). We have demonstrated previously important fibrosis and loss of extracellular matrix (ECM) at the media of FMD arteries. Using less stringent significance threshold (P<0.01), we identified several genes involved in ECM structure, cell shape and junction, which are interesting candidates for FMD. Validation of the identified variants both in statistical and candidate genes is underway.

P01.079

Clinical symptoms in fibromyalgia are associated to catechol-O-methyltransferase (COMT) gene Val158Met polymorphism

*S. Sezer[1], O. Ates[1], **N. Karakus**[1], A. Inanir[2], N. Bozkurt[1], S. Inanir[3], S. Yigit[1];*
[1]Gaziosmanpasa University Faculty of Medicine Department of Medical Biology, Tokat, Turkey, [2]Gaziosmanpasa University Faculty of Medicine Department of Physical Therapy and Rehabilitation, Tokat, Turkey, [3]Gaziosmanpasa University Faculty of Medicine Department of Psychiatry, Tokat, Turkey.

Fibromyalgia syndrome (FMS) is a common chronic widespread pain syndrome mainly affecting women. Genetic risk factors are known to contribute to the etiology of the syndrome. The aim of this study was to explore the frequency and clinical significance of catechol-O-methyltransferase (COMT) gene Val158Met polymorphism in a large cohort of Turkish patients with FMS. The study included 379 patients with FMS and 290 healthy controls. Genomic DNA was isolated and genotyped using polymerase chain reaction (PCR) and restriction fragment length polymorphism (RFLP) analyses for the COMT gene Val158Met polymorphism. The genotype frequencies of COMT gene Val158Met polymorphism showed a small difference between FMS patients and healthy controls (p = 0.047), however the Met/Met genotype was significantly higher in FMS patients than healthy controls (p=0.016, OR: 1.64, 95% CI: 1.09-2.45). No difference was observed for allele frequencies between two groups (p=0.143). Stratification analysis according to clinical features for this disease reveals that weight, FIQ score, algometry (pressure pain threshold) and Raynaud's syndrome, were detected to have statistically significant associations with Val158Met polymorphism (p=0.037, p=0.042, p=0.039 and p=0.033, respectively). Pain sensitivity, measured by algometry, was statistically higher in patients with Met/Met genotype than the patients with Val/Val and Val/Met genotypes (p=0.017). The results of this study suggest that COMT gene Val158Met polymorphism is positively associated with predisposition to develop FMS and play a relevant role in the clinical symptoms of the disease.

Paternally inherited mutations in *GNAS* exons 1-13 lead to severe intrauterine growth retardation (IUGR)

N. Richard[1], *P. Rault-Guillaume[1], A. Molin[1], N. Coudray[1], G. Abeguilé[1], M. Decamp[1,2], C. Colson[1], I. Blanchard[3], N. Gruchy[1,2], H. Mittre[1,2], M. Gerard[1], H. Jüppner[4], M. Kottler[1,2];*
[1]Centre Hospitalier Universitaire, Caen, France, [2]UFR médecine, Université de Caen Basse Normandie, Caen, France, [3]Université de Caen Basse Normandie, Caen, France, [4]Massachusetts General Hospital and Harvard Medical School, Boston, MA, United States.

Maternally inherited, heterozygous mutations in *GNAS*, the imprinted gene complex encoding the alpha-subunit of the stimulatory G protein (Gs), cause pseudohypoparathyroidism type Ia (PHP-Ia), a disorder characterized by resistance toward parathyroid hormone (PTH) and developmental defects referred to as Albright's Hereditary Osteodystrophy (AHO). When inherited paternally, the same heterozygous *GNAS* mutations lead to pseudo-pseudohypoparathyroidism (PPHP), i.e. AHO features in the absence of hormonal resistance. Subcutaneous ossifications (referred to as progressive osseous heteroplasia (POH)) occur predominantly with paternally inherited mutations. Recent studies suggested that paternal mutations are associated with intrauterine growth retardation (IUGR).

Objectives: To confirm and extend earlier findings, we obtained birth weight (W) length (L) and head circumference (HC) for patients, who had been diagnosed with either PHP-Ia (n=26) or PPHP/POH (n=22), and are carrier of *GNAS* mutations on the maternal or paternal allele, respectively. W, L and HC parameters at birth were compared to the French reference charts for girls and boys; results were expressed as Z-scores for gestational age.

Results: The Z-scores for all three parameters at birth (Table) suggest that mutations on the maternal allele affect intrauterine development to a lesser extent than mutations on the paternal allele.

Conclusion: Our cohort shows that *GNAS* mutations on the paternal allele can be responsible for severe IUGR in humans, indicating that paternal *GNAS* transcripts play a major role in the normal feto-placental development.

Table: Birth parameters (Z-scores)

	Weight (W)	Lenght (L)	Head Circumference (HC)
	Mean ± SEM (n)	Mean ± SEM (n)	Mean ± SEM (n)
PHP-Ia (maternal	-0.65 ± 0.25 (26)	-1.14 ± 0.22 (23)	-0.04 ± 0.29 (19)
PPHP/POH (paternal	-2.80 ± 0.24 (22)	-2.34 ± 0.20 (20)	-1.39 ± 0.23 (19)
p	<0.0001	0.0003	0.0009

Pulmonary arterial hypertension (PAH) is a rare and devastating disease, resulting from progressive obliteration of small caliber pulmonary arteries by proliferating vascular cells, and leading to cardiac failure, with an untreated mean survival of less than three years. PAH can complicate other pathological conditions, or can occur in the context of genetic mutations causing heritable PAH, or can be considered as idiopathic (iPAH), which represents approximately 40% of all PAH. Low penetrance dominant BMPR2 mutations are found in ~80% of familial PAH (fPAH), and in ~15% of iPAH which are thereafter considered as heritable PAH. We conducted a Genome-Wide Association Study (GWAS) based on two independent case-control studies for iPAH and fPAH (without BMPR2 mutations) totaling 625 patients and 1,525 healthy individuals, to identify novel genetic factors associated with iPAH and fPAH (i/fPAH). A genome wide significant association was detected at 18q22.3, the risk allele being associated with an odds ratio for i/fPAH of 1.97 [1.59 - 2.45] (P = 7.47 x 10-10). We have shown by immunochemistry and RT-PCR analysis that the closely mapping gene is expressed in the lung, particularly in pulmonary vascular endothelial cells. Furthermore, its expression is increased in explanted lungs from PAH patients and in endothelial cells cultured from explanted PAH lungs. Altogether, these results strongly suggest a role for this gene as a novel contributor to the physiopathology of i/fPAH.

Clinical expression of Hereditary Haemorrhagic Telangiectasia and digestive lesion characteristics in patients with SMAD4 mutation.

M. Bonjean[1], *S. Giraud*[2], *E. Decullier*[3], *J. Saurin*[4], *P. Edery*[1], *S. Dupuis-Girod*[1];
[1]*Hospices Civils de Lyon, Service de Génétique et centre de référence sur la maladie de Rendu-Osler, Bron F-69677, France,* [2]*Hospices Civils de Lyon, Laboratoire de biologie moléculaire, Hôpital E. Herriot, Lyon, F-69437, France,* [3]*Hospices Civils de Lyon, pôle IMER,, Lyon, F-69003, France,* [4]*Hospices Civils de Lyon, Service d'Hépato-gastroentérologie, Hôpital E. Herriot,, Lyon, F-69437, France.*

Backgrounds: Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant vascular disorder characterized by epistaxis, telangiectasia and arteriovenous malformations. Most of HHT cases result from mutations in *ENG* (coding for endoglin) and *ACVRL1* (coding for activin receptorlike kinase 1). In addition, mutations in *MADH4* (encoding SMAD4) which cause a juvenile polyposis /HHT overlap syndrome, have been described. Our aim was to define clinical expression of HHT and digestive lesions in HHT patients with *SMAD 4* mutation followed in the French reference center.

Methods: Restrospective analysis of HHT patients with *SMAD4* mutations. Curaçao criterias were used for HHT diagnosis and Jass criterias for juvenile polyposis.

Results: 14 among 589 patients with identified mutation had *SMAD4* mutation (2.3%). Epistaxis and telangiectasia were present in 13 (93%) and 11 (79%) patients respectively. Nine patients among 13 screened patients had pulmonary arterioveinous malformations (PAVMs) (69%). Among them 4 had diffuse or multiple PAVMs associated with hypoxemia. Three patients among 11 screened patients (27%) had severe hepatic AVM with high cardiac output. Among eleven SMAD4 patients who had digestive endoscopies: 10 (91%) had digestive lesions.

Conclusion: In this study the digestive presentation in patients with SMAD4 mutations is not limited to juvenile polyposis. The HHT phenotype appeared to be more severe for hepatic and pulmonary arteriovenous malformations. This study confirms that any patient with *SMAD4* mutation should be screened for juvenile polyposis or digestive tract cancers as well as for HHT complications.

P01.083

A Molecular Genetic Study of Congenital Lymphedema

S. Melikhan Revzin[1], *E. Dagan*[2], *R. Gershoni-Baruch*[1,3];
[1]*2The Bruce and Ruth Rappaport School of Medicine, Technion, Haifa, Israel,* [2]*Dept of Nursing, Faculty of Welfare and Health Sciences, University of Haifa, Israel, Haifa, Israel,* [3]*Institute of Human Genetics, Rambam Health Care Campus, Haifa, Israel, Haifa, Israel.*

Scientific Background: Primary lymphedema results from a dysfunction of the lymphatic system. Familial lymphedema usually segregates as an autosomal dominant trait, with only one case described in line with autosomal recessive transmission. Genetic studies of families with hereditary lymphedema have yielded mutations in three lymphangiogentic genes: FLT4 (VEGFR3), FOXC2, SOX18. Our research seeks to map and ultimately hunt the mutation that causes hereditary lymphedema in an extended consanguineous Muslim family consisting of four affected individuals: one female, presenting with isolated edema of the lower extremities, and three males presenting with lymphedema of the lower extremities, lymphocele and mild mental retardation.

Material and Methods: After locating a candidate locus using whole genome linkage analysis (Illumina CytoSNP6000 array), Sanger sequencing of the candidate genes was preformed.

Results: A candidate locus of 2.3 Mb located on chromosome 5q35.3 was identified, showing homozygosity in the affected individuals. This locus has been previously linked to congenital lymphedema. Using SUPERLINK online, linkage analysis generated a two-point LOD score of 3.18. Several mutations in the candidate gene, FLT4, previously described in Muslim-Israeli families, were discarded as culprit using sequence analysis. While sequencing FLT4, a missense mutation has been discovered in exon 28 (Ser1235Cys). Unlike other mutations previously described, this mutation is located outside the tyrosine-kinase domains, and has perfect segregation within the family. A population screen for the mutation was performed, with no carriers found in 100 Muslim Israeli-Arabs. Furthermore, a whole-exome analysis of an affected individual revealed no other mutations in lymphedema-related genes.

Pulmonary venoocclusive disease and interstitial fibrosis in a female with Myhre syndrome due to the common SMAD4 mutation: evidence for pathogenic mechanism.

P. Kannu[1], *N. Karp*[1], *E. Cutz*[1], *V. Cormier-Daire*[2], *A. Hinek*[1];
[1]*Hospital for Sick Children, Toronto, ON, Canada,* [2]*Hôpital Necker Enfants Malade, Paris, France.*

Myhre syndrome (MS) is a rare connective tissue disease characterized by short stature, a peculiar body build, hearing loss, joint stiffness, brachydactyly, variable intellectual disability and characteristic skeletal and facial features. A common missense mutation in the MAD homology 2 domain of SMAD4, a gene involved in TGF-β/BMP2 signaling, was recently shown to be causative of the condition. The majority of previously reported individuals are males with only eight females described to date. We report on a female patient with Myhre syndrome identified with the common SMAD4 heterozygous mutation who developed severe pulmonary venoocclusive disease and pulmonary interstitial fibrosis. This respiratory complication has been previously reported only in a single male patient with Myhre syndrome.

We performed in vitro studies on skin fibroblasts from the proband and identified a chain of molecular events triggered by the SMAD4 mutation. The principal defect results in furin deficiency leading to a deficit of a functional form of CD109, which in turn causes a decreased rate of TGF-β receptor degradation. The latter results in an exaggerated response to normal levels of TGF-β1 and higher than normal production of fibrous components of extracellular matrix (elastin, collagen type 1 and fibronectin). We propose that this chain of events contributes to the development of the severe pulmonary, vascular and interstitial disease in Myhre Syndrome.

P01.085

Spherophakia and megalocornea in a German patient with LTBP2 mutations

T. M. Neuhann[1], *A. Stegerer*[1], *M. Smitka*[2], *E. Holinski-Feder*[1], *N. Di Donato*[3];
[1]*Medizinisch Genetisches Zentrum, Munich, Germany,* [2]*Klinik und Poliklinik für Kinder- und Jugendmedizin, Universitätsklinikum Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany,* [3]*Institut für Klinische Genetik, Technische Universität Dresden, Dresden, Germany.*

Mutations in LTBP2 have been originally identified as a cause of primary congenital glaucoma; furthermore mutations were reported in megalocornea, ectopia lentis and secondary glaucoma , in one patient with isolated spherophakia, and most recently associated with features of Weill-Marchesani syndrome . So far only homozygous mutations in patients from consanguineous and Gipsy families were reported. We report on a German boy with spherophakia and megalocornea (corneal diameter LE 14.5 mm; RE 14.5 mm) without other signs of connective tissue disease. Mutation analysis of LTBP2 revealed two mutatios c.688delC; p.(Gln230Argfs*50) and c.1610delC; p.(Pro537Leufs*20). Segregation analysis revealed the presence of one mutation in each parent. Thus, mutations in LTBP2 should be considered not only in patients with primary congenital glaucoma, but more importantly in patients with variable ocular phenotypes including megalocornea, ectopia lentis, and (micro-) spherophakia, also, if extraocular features are present and regardless of the ethnic background.

First description of a homozygous whole gene deletion of COL6A1 gene in a patient with Ullrich Congenital Muscular Dystrophy

D. Wahl[1,2], *U. Heinrich*[1], *C. Uebler*[3], *I. Rost*[1];

[1]*Centre for Human Genetics and Laboratory Medicine, Martinsried, Germany,* [2]*Medical Practice for Genetic Counselling and Psychotherapy, Augsburg, Germany,* [3]*Josefinum Children's Hospital, Augsburg, Germany.*

Ullrich Congenital Muscular Dystrophy (UCMD; OMIM 254090) is a rare neuromuscular disease which is difficult to diagnose by the clinical phenotype being mainly characterized by congenital muscle weakness as well as wasting and proximal joint contractures associated with severe distal joint laxity. We present a girl with congenital general muscular hypotonia - suspected to be syndromic - failure to thrive due to sucking weakness, joint laxity, and discrete dysmorphic features, who was seen by the genetic counsellor for the first time at the age of 4 months. She suffered from bronchopneumonia at the age of 3 ½ months and showed a twofold elevated CK-MB in the course of the laboratory evaluation. Since it was not possible to identify the cause of her symptoms during the counselling interview, array-CGH was performed revealing three chromosomal imbalances - a heterozygous duplication 5q35.3, a heterozygous duplication 16q12.2 and a homozygous deletion 21q22.3. The deletion spans 56,94 kb of genomic DNA and contains the COL6A1 gene, one of the three causative genes in UCMD. Array-CGH of the parents revealed both as carriers of the deletion 21q22.3 though consanguinity was denied by the parents. This case demonstrates the possibility to detect a recessive monogenic disease by array-CGH. To the best of our knowledge this is the first case of UCMD due to a homozygous deletion of COL6A1. The causality of this deletion is very probable, because nonsense mutations leading to a lack of the COL6A1 gene product have been already described as a reason for UCMD.

NSAIDs-induced acute urticaria/angioedema: Genome-wide association study in Spanish and Han-Chinese populations

J. A. Cornejo-Garcia[1], *M. Lee*[2], *Y. Chen*[3], *N. Blanca-López*[4], *I. Doña*[5], *M. J. Torres*[5], *C. Rondón*[5], *P. Campo*[5], *J. J. Laguna*[6], *J. Fernández*[7], *V. Godineau*[1], *P. Ayuso*[4], *M. C. Plaza-Serón*[1], *M. Gandolfo*[8], *A. Rosado*[9], *G. Canto*[4], *C. Mayorga*[1], *M. Blanca*[5];

[1]*Research Laboratory, UGC Allergy, Málaga General Hospital, Málaga, Spain,* [2]*Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan,* [3]*Institute of Biomedical Sciences, Academia Sinica, Taipei, Spain,* [4]*Allergy Service, Infanta Leonor Hospital, Madrid, Spain,* [5]*UGC Allergy, Málaga General Hospital, Málaga, Spain,* [6]*Allergy Service, Cruz Roja Central Hospital, Madrid, Spain, Madrid, Spain,* [7]*Allergy Service, Alicante Hospital, Alicante, Spain, Alicante, Spain,* [8]*Allergy Service, Fuenlabrada Hospital, Madrid, Spain,* [9]*Allergy Service, Alcorcón Foundation-Hospital, Madrid, Spain.*

Background: Acute urticaria/angioedema (AUA) induced by cross-intolerance (CI) to NSAIDs is the most frequent clinical entity in hypersensitivity reactions (HRs) to drugs. However, most of genetics studies in NSAIDs HRs have been carried out in patients with aspirin-induced asthma, mainly in Asian populations, and have followed the candidate gene approach.
Objective: We conducted a genome-wide association study (GWAS) in two ethnically different populations of Spanish and Han-Chinese patients suffering from NSAIDs-induced AUA.
Methods: We included a total of 232 cases (112 from Spain and 120 from Taiwan) with NSAIDs-induced AUA, without airway involvement or underlying chronic urticaria, and 225 unrelated controls (124 from Spain and 101 from Taiwan). Whole-genome scan was performed using Affymetrix® Genome-wide Human SNP Array 6.0 (Affymetrix, Santa Clara, CA, USA).
Results: We obtained suggestive associations for a total of 3 clusters in the Spanish group (RIMS1, BICC1, and RAD51L1), whereas one main region was identified in the Han-Chinese population (ABI3BP). Five regions showed suggestive associations after meta-analysis: HLF, RAD51L1, COL24A1, GalNAc-T13, and FBXL7. Some of these genes are related with Ca++ channels and cAMP signaling pathways.
Conclusions: The associations described with genetic variants different from those related with the metabolism of the arachidonic acid open up new potential pathways for understanding the mechanisms underlying NSAID-induced AUA.

Copy number variants in patients with abdominal aortic aneurysms

D. F. Majoor-Krakauer[1], *K. M. van de Luijtgaarden*[2,3], *H. J. M. Verhagen*[2], *R. J. Stolker*[4], *G. C. M. Huijbrechts*[1], *L. Koster*[1], *A. M. Bertolli Aveda*[1], *B. H. B. Berveloo*[1], *L. J. C. M. van Zutven*[1];

[1]*Department of Clinical Genetics, Erasmus University Medical Center, Rotterdam, Netherlands,* [2]*Department of Vascular Surgery, Erasmus University Medical Center, Rotterdam, Netherlands,* [3]*Department of Anesthesiology, Erasmus Univeristy Medical Center, Rotterdam, Netherlands,* [4]*Department of Anesthesiology, Erasmus University Medical Center, Rotterdam, Netherlands.*

Abdominal aortic aneurysms (AAA) are a major cause of morbidity and mortality in the elderly and are characterized by extracellular matrix (ECM) degeneration, dysregulation of vascular smooth muscle (SMC) cells, inflammation and atherosclerosis. In approximately 20% of cases abdominal aneurysm are familial (fAAA). The genes involved in fAAA have not been identified sofar. The aim of the current study was to investigate if copy number variants (CNV) may add in discovering pathofysiologic pathways and genes involved in AAA formation.
AAA patients referred for genetic counseling in 2011 and 2012 were included. Patients were classified as familial when at least one first-degree was reported to have an aortic aneurysm. Patients without a positive family history were classified as sporadic (spAAA). Microarray was performed in the index patient and in case of a CNV, also affected relatives were analysed, when possible.
Microarray was performed by using the Illumina HumanCytoSNP-12v2.1 and analysed using Nexus CopyNumber Discovery v6.1 software. Results were evaluated using the UCSC Genome Browser March 2006, the Database of Genomic Variants and an in-house database of controls. Inguinuity pathway (IPA) pathway analysis was performed of genes identified in rare CNV regions.
Results: The study population consisted of 77 index AAA patients; 62 were classified as fAAA and 15 as spAAA. We found 19 rare CNV variants in 14 (23%) of the fAAA patients and in one (7%) spAAA. The CNV's and the genes localized in the affected regions will be presented together with the IPA pathway analysis.

Elastin gene mutations have been associated with a variety of phenotypes. Autosomal dominant cutis laxa (ADCL) is a rare disorder that presents with typical facial characteristics, inguinal hernias, aortic root dilatation and pulmonary emphysema. In most patients, frameshift mutations are found in the 3' region of the elastin gene (exons 30-34) which result in a C-terminally

extended protein, though exceptions have been reported.
We clinically and molecularly characterized the thus far largest cohort of ADCL patients, consisting of 19 patients from six families and one sporadic patient.
Molecular analysis showed C-terminal frameshift mutations in exon 30, 32, and 34 of the elastin gene and identified a mutational hotspot in exon 32 (c.2262delA). This cohort further confirms the previously reported clinical constellation of skin laxity (100%), inguinal hernia (51%), aortic root dilatation (55%) and emphysema (37%).
In conclusion, ADCL is a clinically and molecularly homogeneous disorder, but intra- and interfamilial variability in the severity of organ involvement needs to be taken into account. Regular cardiovascular and pulmonary evaluations are imperative in the clinical follow-up of these patients.

Severe Congenital Lipodystrophy and Progeroid Appearance: Mutation in the Penultimate Exon of FBN1 Causing a Recognizable Phenotype

R. Kosaki[1], *T. Takenouchi*[2], *K. Kosaki*[3];
[1]*Division of Medical Genetics, National Center for Child Health and Development Hospital, Setagaya, Tokyo, Japan,* [2]*Department of Pediatrics, Keio University School of Medicine, Shinjuku, Tokyo, Japan,* [3]*Center for Medical Genetics, Keio University School of Medicine, Shinjuku, Tokyo, Japan.*

Recently, three Marfanoid patients with congenital lipodystrophy and a neonatal progeroid appearance were reported. Although their phenotype was distinct from that of classic Marfan syndrome, they all had a truncating mutation in the penultimate exon, i.e., exon 64, of FBN1, the causative gene for Marfan syndrome. These cases might represent a new entity, but the exact phenotypic and genotypic spectrum remains unknown. Here, we report a girl born prematurely who exhibited severe congenital lipodystrophy and a neonatal progeroid appearance. The patient exhibited a peculiar growth pattern consisting of an accelerated growth in height with a discrepant poor weight gain. She had a characteristic facial appearance with craniosynostosis. A mutation analysis identified c.8175_8182del8bp p.Arg2726Glufs*9 in exon 64 of the FBN1 gene. A review of similar, recently reported patients revealed that the cardinal features of these patients includes 1) congenital lipodystrophy, 2) premature birth with an accelerated linear growth disproportionate to the weight gain, and 3) a progeroid appearance with distinct facial features. Lines of molecular evidence suggested that this new progeroid syndrome represents a neomorphic phenotype caused by truncated transcripts with an extremely charged protein motif that escapes from nonsense-mediated mRNA decay, altering FBN1-TGF beta signaling, rather than representing the severe end of the hypomorphic phenotype of the FBN1-TGF beta disorder spectrum. We propose that this Marfanoid entity comprised of congenital lipodystrophy, a neonatal progeroid appearance, and a peculiar growth prolife and caused by rare mutations in the penultimate exon of FBN1 be newly referred to as Marfanoid-progeroid syndrome.

Homozygous *LMNA* lipodystrophy

Y. M. Hoedemaekers[1,2], *L. P. V. Berger*[2], *J. Langendonk*[2], *E. Brusse*[2], *M. Michels*[2], *M. van Slegtenhorst*[2], *G. Mancini*[2], *Y. van Bever*[2];
[1]*UMCG, Groningen, Netherlands,* [2]*Erasmus MC, Rotterdam, Netherlands.*

Background:
Heterozygous *LMNA* mutations cause a broad spectrum of diseases such as progeria, muscular dystrophies, dilated cardiomyopathy and lipodystrophy. Lipodystrophy is characterised by loss of subcutaneous fat from limbs and trunk and a tendency to insulin resistance, dyslipidemia and hypertension. So far homozygous *LMNA* mutations causing lipodystrophy have not been described.
Methods and results:
We report the first two lipodystrophy patients with homozygous *LMNA* mutations. The index patient was referred under the suspicion of mosaic Turner syndrome. She had hypertension and hypercholesterolemia. Her build showed typical partial lipodystrophy and a homozygous mutation was identified in the *LMNA* gene (R582H). Subsequent cardiac and neurologic examinations were normal. The brother of the index patient was diagnosed with diabetes mellitus type I, hypertension and hypercholesterolemia at the age of 27 years. He had the same characteristic build and was also homozygous for the R582H mutation in *LMNA*. Molecular diagnostics identified heterozygous *LMNA* mutations in both parents, who were unaware of consanguinity. The father had a mild lipodystrophy build without other disease characteristics; the mother had hypertension and hypercholesterolemia without the typical build.
Conclusion:Homozygous *LMNA* mutations causing lipodystrophy show slight intrafamilial variability in phenotype and do not seem to cause a more severe phenotype than heterozygous *LMNA* mutations.

Loeys-Dietz syndrome caused by a *TGFB2* mutation: further delineation of the phenotype

S. Salemink[1], *M. Kempers*[1], *D. Schepers*[2], *L. van Laer*[2], *B. Loeys*[1,2];
[1]*Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [2]*Center for Medical Genetics, Faculty of Medicine and Health Sciences, University of Antwerp and Antwerp University Hospital, Antwerp, Belgium.*

Loeys-Dietz syndrome (LDS) is a rare autosomal dominant connective tissue disorder which has many features in common with Marfan syndrome (MFS). The disease is typically characterized by the triad of arterial tortuosity and aneurysms, hypertelorism, and bifid uvula or cleft palate. In most cases, LDS is caused by heterozygous mutations in genes encoding positive effectors of TGFβ signaling, including the subunits of the TGFβ receptor *TGFBR1* and *TBFBR2* or *SMAD3.* Most recently, we showed that loss-of-function mutations in the gene encoding the TGFβ2 ligand can also cause a phenotype within the LDS spectrum.
Here we describe the phenotypic characteristics of a large family (n=9 affected individuals) with a *TGFB2* mutation (c.1097 C>A; p.Pro366His). Within this family we observe a variable clinical expression with near absent to severe cardiovascular involvement. The main clinical features shared with MFS include aortic aneurysm, pectus deformity, arachnodactyly, scoliosis and skin striae. Clinical features other than in MFS include hypertelorism, bifid uvula, bicuspid aortic valve, arterial tortuosity, club feet and thin skin with easy bruising. Ectopia lentis was not observed. Compared to LDS patients with a *TGFBR1, TGFBR2, SMAD3,* patients with a *TGFB2* mutation do present rather mild aortic disease, more frequent mitral valve disease and increased incidence of club feet.

P01.094

Coexistence of pathogenic mutations in APC and NF1 in the same patient.

C. Jimenez Criado;
Centro de Investigacion del Cancer, Salamanca, Spain.

Neurofibromatosis type I is a rare genetic disorder that causes benign tumors on nerves and other skin and bone manifestations. NF1 gene mutations cause this disease. Familial adenomatous polyposis (FAP) is a rare inherited disease characterized by the appearance of more than 100 colonic polyps. APC mutations are responsible of increased risk of FAP.
We report the case of a 20 years old woman with pink polypoid lesions associated with a possible neurofibromatosis type I. The patient had a preventive total colectomy due to maternal inherited, surgeries due to cysts and epidermal Trichilemmal and a abdominal laparotomy due to a desmoid tumor.
We analyzed DNA extracted from peripheral blood and from neurofibroma. The neurofibroma showed the presence of a pathogenic NF1 mutation (c.5418_5422delGGGC / p.Q1806QfsX) that produces a stop codon, resulting in a truncated protein responsible of the disease. Moreover, analysis of APC showed a second pathogenic mutation (c.3783_3785delTT/p.T1261TfsX) that produces a stop codon in the position 1273. The resulting a truncated protein is believed to cause increased risk of FAP. Neither of the two mutations were described previously.
Thus we present a case of a woman carrying a germline mutation in the APC gene and a somatic mutation in the NF1 gene that could generate a somatic mosaicism and explain the presence of two hereditary diseases in the same patient.
Supported FIS PI 10/00219

Pathogenic mutations		
Sample	APC study	NF1 study
DNA from peripheral blood	c.3783_3785delTT/p.T1261TfsX	No mutations
DNA from tumor	c.3783_3785delTT/p.T1261TfsX	c.5418_5422delGGGC/p.Q1806QfsX

P01.095

Neurofibromatosis type 1 gene mutation analysis using sequence capture and high throughput sequencing.

E. Jokinen[1], *A. Hammais*[1], *E. Palonen*[2], *V. Mäkelä*[2], *E. Jouhilahti*[1], *A. Brandt*[2], *J. Soini*[2], *J. Peltonen*[1], *S. Peltonen*[3];
[1]*Department of Cell Biology and Anatomy, University of Turku, Turku, Finland,* [2]*Molecular Diagnostics Laboratory, Turku University of Applied Sciences, Turku, Finland,* [3]*Department of Dermatology, University of Turku and Turku University Hospital, Finland, Turku, Finland.*

Background: Neurofibromatosis type 1 syndrome is caused by mutations in the *NF1* gene. More than thousand pathogenic mutations have been published. At present, diagnostic laboratories use traditional sequencing methods, which often require fresh blood, or tissue sample.
Aims: The aim of this study is to develop an *NF1* mutation analysis method which does not require invasive sampling and is performed with lower costs than the traditional methods.
Methods: Genomic DNA (gDNA) of 16 NF1 patients was isolated from saliva using saliva sampling (Oragene, DNA Genotek). *NF1* exome with additional 50 nucleotides of flanking intronic sequences was captured and enriched using SeqCap EZ Choice Library protocol (Roche Nimblegen). Captured DNA was sequenced with Roche/454 GS Junior system in two sample sets of different size (6 and 10 samples).
Results: The average coverage of targeted regions was 41x (10 samples) and 74x (6 samples). A putative mutation was discovered in 10 samples out of the total 16. In addition, evidence of one known microdeletion was observed.
Conclusions: Our study provides proof of principle that the sequence capture methodology combined with high-throughput sequencing is applicable to *NF1* mutation analysis. The advantages include that saliva sampling is noninvasive and the samples can be sent to the laboratory via regular mail. The limitations include that deep intronic mutations may be undetectable and change at the DNA level does not always predict the outcome at the mRNA or protein levels.

A Family With Basex-Dupré-Christol Syndrome with Persistent Milia

A. Kuskucu[1], *M. Ugras*[2], *A. Vitrinel*[2];
[1]*Yeditepe University School of Medicine Department of Medical Genetics, Istanbul, Turkey,* [2]*Yeditepe University School of Medicine Department of Pediatrics, Istanbul, Turkey.*

Bazex-Dupré-Christol Syndrome (BDCS) is a rare X-linked dominant inherited genodermatosis with cancer predisposition, characterized by follicular atrophoderma, congenital hypotrichosis, milia and basal cell malformations.
We present a three-generation family without a diagnosis until index case was referred to our center from department of pediatrics. Index case was nine months old boy and third child of the non-consanguineous parent. He has persistent milia and congenital hypotrichosis. He has two healthy brothers. His mother and maternal aunt had milia until age 2. There is a family history of congenital hypotrichosis, follicular atrophoderma and basal cell carcinoma on his mother, maternal grandfather and grandaunt and maternal cousins. The differential diagnosis of BDCS includes other hereditary syndromes associated with the development of BCCs at early age, such as basal cell nevus syndrome, Rombo syndrome, Oley syndrome and Xeroderma pigmentosum.
Based on the clinical findings of index case, family history and inheritance pattern we diagnosed the family as BDCS. To the best of our knowledge, about 20 families referred to as BDCS and this is the third family from Turkey with BDCS.

A. Kuskucu: None. **M. Ugras:** None. **A. Vitrinel:** None.

P01.097

Familial presentation of Cartilage-Hair Hypoplasia (Metyaphyseal chondrodysplasia Mckusick type)

A. M. Gómez Pastor, *M. L. Quitanilla Mata, L. Sánchez Gancedo, M. L. González Moral, L. Navarro Casado;*
Servicio de Análisis Clínicos.Hospital General de Albacete, Albacete, Spain.

INTRODUCTION:
Cartilage-hair hypoplasia (CHH) is an autosomal recesive disorder affecting the bone metaphyses, causing small stature from birth and sometimes immune deficiencies. The CHH-AD spectrum includes a range of phenotypes: metaphyseal dysplasia without hypotrichosis (MDWH), CHH and anauxetic dysplasia (AD) with the most pronounced skeletal phenotype.
Mutations in the *RMRP* gene are responsible for the disease.
CASE:
Proband 30 months old with short stature, low weight, blonde, fine silky hair, laxity of ligaments with hypermobility of joints and short thick tubular bones. Father diagnosed of metaphyseal chondrodysplasia Schmid type (MCDS) in childhood. Proband´s mother has normal phenotype, but several maternal relatives with clinical diagnosis of CHH. No evidence of consanguinity. Sequence analysis of the *RMRP* showed the following results:
Proband: *RMRP* c.70A>G (homozygous)
Father: *RMRP* c.70A>G and c.4C>T (compound heterozygous)
Mother: *RMRP* c.70A>G (heterozygous)
Genetic study was extended to the family of the mother. Neither of her two sisters was carrier of the mutation c.70A>G. but both of them were c.4C>T (heterozygous). The molecular study of their parents showed that the mother was compound heterozygous for mutations c.70A>G and c.4C>T and had short stature.
The father´s proband had normal hair and was diagnosed of MCDS. The molecular study showed that the disease was in fact MDWH, which could explain the confusion in the diagnostic.
CHH-AD disorder has a high incidence in certains populations with consaguinity (Amish 1-2:1000). In this family there was no evidence of consanguinity but they come from a small village of aproximately 10000 inhabitants.

Smith–McCort dysplasia (SMC) is a rare autosomal recessive skeletal dysplasia characterized by a short limbs and trunk dwarfism with a barrel-shaped chest and specific radiological appearance. Skeletal features of SMC are identical to those of Dyggve–Melchior–Clausen syndrome (DMC) but with normal intelligence and no microcephaly. SMC and DMC were shown to be allelic disorders that both result from mutations in the *DYM* gene, which encodes the Golgi protein DYMECLIN. However, a few SMC patients remained negative in *DYM* mutation screening. Recently, autozygosity mapping and exome sequencing in a large consanguineous SMC family have allowed the identification of a missense mutation in the *RAB33B* gene. This gene encodes another Golgi protein which belongs to the large Rab family of small GTP-binding proteins involved in defined steps of vesicular transport including protein secretion and endocytosis. Here, we report a novel missense mutation in a SMC case that affects the GTP-binding domain of *RAB33B* and leads to a marked reduction of the protein. These data confirm the genetic heterogeneity of SMC dysplasia and highlight the role of Golgi transport in the pathogenesis of SMC and DMC syndromes. Our results also raise the question of whether the *RAB33B* gene would account exclusively for SMC, suggesting that mental retardation and microcephaly would be mainly associated with a complete loss-of function of the *DYM* gene. Analyses in additional cases of SMC and DMC syndromes are now required to answer this question.

Mutations in *COL2A1* in a Brazilian cohort of patients with typical phenotypes of the type 2 collagenoapthie spectrum

K. C. Silveira[1], *L. C. Bonadia*[1], *C. A. Moreno*[1], *C. Steiner*[1], *M. T. V. Sanseverino*[2], *E. Mattos*[2], *D. R. Bertola*[3], *G. Yamamoto*[3], *A. A. L. Jorge*[3], *D. P. Cavalcanti*[1];
[1]*Universidade de Campinas, Campinas, Brazil,* [2]*Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil,* [3]*Universidade de São Paulo, São Paulo, Brazil.*

Heterozygous mutations in *COL2A1* can produce different phenotypes, but with the same pattern known as type-2 collagenopathies. Although the clinical-radiological pattern is recognizable, the correlation genotype-phenotype still needs additional studies. In order to better understand the molecular basis of type-2 collagenopathies the aim of this investigation was to study a cohort of patients with suggestive phenotype of type-2 collagenopathies. The most phenotypes of the 2 collagen spectrum are represented in the 13 patients here reported. Molecular analysis was performed by direct sequencing of the known hot spots of the *COL2A1* according to the phenotype. So far four new mutations have been found - two point mutations (c.1438G>C - p.G480A, c.1546G>A - p.G516S) associated with SEDC, a T-to-G transversion (p.C1315G) in a patient with Torrance dysplasia (TD), and a deletion (4387_4389delATT - Ile1463del) also associated with TD. These last two mutations are placed in the C-propeptide domain. In addition, six previously described mutations were found, two transitions with a glycine substitution in the triple helix domain [SEDC and ACGII], three identical C-to-T transitions - p.R989C associated with SEMD phenotype, also called Strudwick dysplasia, and a deletion (g.899_924+2del) in a patient with Kniest dysplasia (KD). Finally, for three cases (KD, Hypochondrogenesis, and SEDC) no mutations were found on the respective hot spots and the complete sequencing of *COL2A1* is ongoing. In conclusion, four new mutations in *COL2A1* were found contributing to a better understanding about the type-2 collagenopathies spectrum.

Lysosomal Cathepsin A deficient mouse model shows altered vasoactive peptid Endothelin I (ET-1) level in serum and organs

V. Seyrantepe*, M. Delman, Z. Timur, S. Akyildiz, S. Ozturk;*
Izmir Institute of Technology, İzmir, Turkey.

Cathepsin A is lysosomal enzyme that makes complex with α-neuraminidase and β-galactosidase. It has also carboxypeptidase activity catalyzing the hydrolysis of C-terminal peptide bond, potentially affects vasoactive peptide actions in normal and pathological conditions. In order to elucidate the biological function of Cathepsin A in vivo, previously we generated knock-in mouse model with catalytically inactive Cathepsin A protein. We showed that Cathepsin A-/- mice have significantly increased arterial blood pressure and higher level of ET-1 secreted from cultured brain cells. In this work we present our further study of ET-1 levels from serum and four organs including lung, kidney, liver and brain of 3 and 6-months old male Cathepsin A-/- mice (n=6-7) and age matched wild-type mice (n=7). Our ELISA data shows that ET-1 level is slightly higher in liver and brain tissues of 3 months as well as in kidney and brain tissues of 6 months old Cathepsin A-/- mice compared to wild-type mice. Interestingly, although there is no difference in the serum ET-1 level between 3 and 6 months old wild type mice, five times lower ET-1 level in serum of 6-months compared to 3-months old Cathepsin A-/- mice may suggest the contribution of other carboxypeptidases such as homologous Scpep1 for the degradation of ET-1 in aging mice. The detailed analysis of other vasoactive peptides including substance P in different organs of CathepsinA-/- mice will be valuable to understand better the physilogical role of Cathepsin A in the modulation of vasoactive peptides and complex processes regulating blood pressure.

Comprehensive characterization of a zebrafish model for pseudoxanthoma elasticum role reveals a role for the abcc6 transporter in cardiovascular development

M. J. Hosen*, A. Willaert, P. J. Coucke, A. De Paepe, O. M. Vanakker;*
Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Background. Pseudoxanthoma elasticum (PXE) is characterized by elastic fiber calcification and fragmentation, resulting from ABCC6 mutations. Recently, upregulation of the pro-osteogenic BMP2-RUNX2 pathway was demonstrated in patients. Also, recent reports on vascular malformations in patients suggested a possible developmental role for ABCC6.
Methods and results. We used 4 zebrafish (ZF) models, targeting each of 3 abcc6 isoforms and a combined knock-down, to assess the developmental phenotype, mineralization and mineralization-associated pathways. In-situ Hybridisation demonstrated all isoforms to be mainly expressed in the pronephric ducts. Abcc6 knock-down was obtained by injecting translational blocking or splice junction morpholinos in 1-4 cell stage embryos. Morphants exhibited a delay in gastrulation. At 3 days post fertilization (dpf), curving and shortening of the tail, variable in severity, pericardial edema, decreased mobility, total body length and body pigmentation as well as underdevelopment of head and eyes were observed. Cardiovascular evaluation, using MO injection on Fli:gfp embryos demonstrated the development of a rudimentary tubular heart compared to controls, contributing to early demise of the morphants. Further, underdevelopment and delayed sprouting of multiple vessels was noted. Calcein staining of the morphants (5dpf) showed advanced skeletal mineralization compared to controls. QPCR analysis revealed upregulation of BMP2a, RUNX2a and MSXc.
Conclusion. We illustrate a distinct phenotype, affecting longitudinal growth, eye and cardiovascular development. The cardiovascular underdevelopment in the morphants corroborate the hypothesis that ABCC6 may also have an embryological role. Advanced mineralization and confirmation of BMP2-RUNX2 involvement suggest that ZF is a useful model organism for further PXE cell signalling research.

Two unusual manifestations in Sturge-Weber Syndrome: ipsilateral retinal vascular anomalies and cerebellum calcifications

C. M. Jurca[1,2], *K. Kozma*[1,2], *D. Bembea*[1], *A. Jurca*[1], *C. Cladovan*[1,2], *I. Drăgan*[2], *M. Bembea*[1,2];
[1]*University from Oradea, Faculty of Medicine and Pharmacy, Oradea, Romania,*
[2]*Municipal Clinical Hospital "dr. G. Curteanu", Oradea, Romania.*

Introduction. Sturge-Weber syndrome is a rare genetic disorder (frequency 1:50,000 newborns) with unknown etiology. Also called encephalotrigeminal angiomatosis, it is characterized by facial hemangioma (Porto wine stain) extending to the supraorbital region and associated with eye abnormalities and leptomeningeal angiomatosis. **Objective.** To present a case of Sturge-Weber syndrome associated with unusual retinal vascular abnormalities and cerebellum calcifications. **Methods**. Case report. **Results**. A 12-year-old girl who presented at birth with a hemangioma extending from the left hemiface, including over- and periorbital regions, to the neck, ear, cheek, lower lip and chin. Ophthalmologic examination showed anomalies exclusive to the left eye: secondary glaucoma and fundus vascular anomalies: tortuous and dilated veins, arteries „in vortex" around veins and pseudoneovascularisation. CT revealed multiples calcifications in the ipsilateral cerebellum. **Conclusion**. The case presented shows two unusual manifestations of Sturge-Weber syndrome: ipsilateral retinal vascular anomalies and multiple calcifications in the ipsilateral cerebellum.

Association of hereditary thrombocytosis and transverse limb deficiency in three independent families with THPO mutations

C. Graziano[1], *M. David*[2], *C. Stockklausner*[3], *P. Magini*[1], *J. Baptista*[1], *M. Romagnoli*[1], *T. Pippucci*[1], *A. Kulozik*[3], *A. Superti-Furga*[4], *M. Seri*[1];

Hereditary thrombocytosis, usually inherited as a dominant trait, can be caused either by heterozygous mutations in the thrombopoietin gene (THPO) or by heterozygous mutations in the THPO receptor MPL. Germline mutations in THPO identified so far affect the 5'-UTR and remove the ORFs upstream of the regular translation start, which have an inhibitory effect on translation. As a consequence, the mutations result in increased translation of the THPO m-RNA and overproduction of platelets.
Vascular disruption is believed to be the most common cause of unilateral limb deficiency, usually a sporadic birth defect. We describe three families where thrombocytosis caused by a dominant THPO mutation is associated

with unilateral transverse limb defects in multiple affected family members. We hypothesize an involvement of THPO signaling in embryo vasculature development, since THPO was identified as a critical factor for the proliferation of the hemangioblast, the embryonic progenitor of hematopoietic and endothelial lineages. THPO excess may thus alter vasculogenesis, conferring predisposition to vascular disruptions.
We speculate that this could be possible on a specific genetic background, since the same pathogenetic mechanism (THPO overproduction) is observed in large families with isolated thrombocytosis. This speaks against a simple direct relationship between the THPO mutation and the limb defects and suggests the necessity of an additional common genetic variant in the determination of limb defects. In order to address this issue, we are undertaking NGS analysis to compare family members with thrombocytosis only and those with thrombocytosis plus limb deficiency.

COL3A1 mutations commonly cause obvious vascular EDS phenotypes; cutaneous thinning, vascular fragility and rupture, especially of large and medium sized arteries. Dermal histology, (light and electron microscopy), shows characteristic changes in collagen morphology, Collagen protein analysis from cultured skin fibroblasts may show procollagen and collagen type III deficiency. COL3A1 gene sequencing identifies helical glycine missense substitutions, exon skips or rare variably sized COL3A1 deletions. Here we describe five patients with unusual clinical phenotypes and novel COL3A1 mutations. Case 1 with a COL3A1 substitution, c.1771G>C, p.(Gly591Arg) had an unexpectedly mild clinical course, having ruptured her aorta at age 42, during a femoral embolectomy; she has survived for 25 years with no further complications. Case 2 with glycine substitution c.3256G>T, p.(Gly1086Cys) had infantile talipes equinovarus and features consistent with BHS/EDS III. A routine colonoscopy perforated his sigmoid colon, subsequent imaging showed an asymptomatic iliac artery aneurysm. Case 3 with an X position mutation c.2044G>A, p.(Glu582Lys) presented with spontaneous oesophageal rupture at age 43 and generalised external features consistent with Classical EDS. Electron microscopy showed no collagen rosettes, collagen V gene sequencing was normal. The COL3A1 mutation segregates in a large autosomal dominant pedigree, with occasional intestinal fragility. Case 4 has a splice donor site mutation c.(1923+2_1923+5del); his childhood clinical features resembled Classical EDS. Later, he perforated a diverticulum at age 19, eventually requiring a total colectomy. Case 5 with an X position mutation c.2513C>T, p.(Pro838Leu) presented with bilateral carotid artery dissection and features consistent with BHS/EDS III.

Mutation analysis of TGFβ pathway genes in Hereditary Hemorrhagic Telangiectasia patients in Japan: Genotype-phenotype correlations in 119 cases

H. Morisaki[1], *M. Komiyama*[2], *O. Yamada*[3], *K. Osuga*[4], *T. Morisaki*[1,5];
[1]*National Cerebral and Cardiovascular Center Research Institute, Suita, Japan,* [2]*Osaka City General Hospital, Osaka, Japan,* [3]*National Cerebral and Cardiovascular Center, Suita, Japan,* [4]*Osaka University Graduate School of Medicine, Suita, Japan,* [5]*Osaka University Graduate School of Pharmaceutical Sciences, Suita, Japan.*

Hereditary Hemorrhagic Telangiectasia (HHT) is an autosomal dominant disease characterized by recurrent epistaxis, mucocutaneous telangiectasia and visceral arteriovenous malformations. The majority of cases are caused by mutations in either endoglin (*ENG*) or activin receptor-like kinase 1 (*ACVRL1*) gene, while mutations in *SMAD4* are seen in patients with the combined syndrome of juvenile polyposis and HHT. We have screened for mutations in a total of 80 unselected Japanese index cases with the suspected diagnosis of HHT. Mutation analysis was performed using direct sequencing of exonic regions and gene dosage analysis with MLPA probes. *ENG* mutations and *ACVRL1* mutations were identified in 47 cases (59%) and 23 cases (29%), respectively. Two cases were associated with *SMAD4* mutations, and 1 case was caused by a mutation in the other TGFβ signaling molecule. In total, disease causing mutations were identified in 73 index cases (91%). 66% of *ENG* mutations were predicted to cause premature termination with nonsense, frameshift, or out-of -frame deletion mutations, while 65% of *ACVRL1* mutations were missense or in-frame deletion mutations. Families study added another 46 mutation-positive cases and genotype-phenotype correlation analysis was performed in a total of 119 genetically defined HHT patients. Pulmonary arteriovenous malformation (PAVF) and cerebral arteriovenous malformation (CAVF) were observed significantly more frequently with *ENG* mutation carriers than *ACVRL1* mutation carriers (PAVF: 85% vs. 30%; CAVF: 33% vs. 11%), while hepatic arteriovenous malformation was significantly more common among *ACVRL1* mutation carriers (11% vs. 45%). This is the first and largest Japanese national study with genetically defined HHT.

Vascular Ehlers-Danlos syndrome (vEDS) is a dominantly inherited connective tissue disorder, characterized by thin, translucent skin, easy bruising, typical facies and arterial/intestinal/uterine fragility and ruptures. Defects in type III procollagen (encoded by *COL3A1*) underlie vEDS and mostly comprise glycine-substitutions in the collagen triple-helical domain. While currently two *Col3a1*-/- mice models have been generated, no mouse model is available for the typical glycine-substitutions.
We generated a transgenic mouse model harboring the p.Gly183Ser-substitution (*Col3a1*-c.547G>A), which was identified in several vEDS patients. Five *Col3a1*-transgenic mouse lines were produced, each harboring different *Col3a1*-transgene copies, of which line 1 mice carried the highest transgene-copy number. Line 1 mice had a decreased pre-weaning survival in comparison to WT-mice (p-value<0.05) and male mice were smaller at age 12- and 16-weeks when compared to WT-mice (12 and 16.2%, respectively). Additionally, line 1 transgenic males displayed a fragile, thin skin and spontaneously developed severe transdermal wounds progressing from the shoulder area to the abdomen. Tensile strength measurements demonstrated that the mechanical properties (e.g. maximum load, extensibility, stiffness, relative failure energy) of the skin and aorta were significantly decreased, thereby confirming the observed fragility when handling both tissues. Ultrastructural data of the dermis showed a disorganised aspect of the extracellular matrix and an increased variability in collagen fibril diameter, which demonstrates disturbed collagen fibrillogenesis. Dilatation of the endoplasmic reticulum of dermal fibroblasts was also seen, which implies the involvement of ER-stress in the observed phenotype.
In conclusion, the phenotype of this transgenic *Col3a1*-mouse model faithfully recapitulates that of human vEDS.

Emotional reactions to genetic testing for vascular Ehlers-Danlos Syndrome in young adults

K. Lahlou-Laforet[1,2], *J. Albuisson*[2,3], *J. M. Mazzella*[2], *X. Jeunemaitre*[2,3], *M. Franck*[2], *S. M. Consoli*[1,3];
[1]*C-L Psychiatry Department, PARIS, France,* [2]*Centre de Référence des Maladies Vasculaires Rares - HEGP, Paris, France,* [3]*Faculté de Médecine Paris Descartes, Paris, France.*

Introduction and Objectives: Vascular Ehlers-Danlos (vEDS) syndrome is a rare and autosomal dominant arterial disease. The occurrence of organ rup-

tures in young adults reduces life-expectancy. Thus genetic testing for vEDS may have an important psychological impact. Our study aimed to evaluate the emotional consequences of a positive genetic testing and to compare emotional reactions according to sex.
Population and Methods: This study included consecutive patients with a positive COL3A1 mutation diagnosed in our centre between 2003 and 2012. Our multidisciplinary testing procedure included a systematic psychiatric visit after the announcement of the molecular diagnosis. Psychiatric minutes were retrospectively reviewed for type of emotional reaction (adapted, trivialization, depression) and nature of the predominant preoccupation (transmission to offspring; limitation of physical activities; other preoccupation).
Results: Thirty-eight patients aged 18 to 40 years (n=26 females) were included in the study. Predominant reaction to diagnosis was depression, n=17 (45%), especially for women: n=16 (62%) vs. n=1(8.3%) in men. Antidepressive therapy was necessary in n=11 (29%) patients. Trivialization was observed in n=7(19%) patients: 7/12 men vs. 0/26 women (p<0.001). Risk of transmission was the first preoccupation in 19/26 women and 2/12 men, followed by limitation of physical activity, expressed by 5/12 men vs. 0/26 women (p<0.001). Depression and risk of transmission were associated.
Conclusions: Diagnosis of vEDS is associated with a high rate of depression. Emotional reactions significantly differed between genders. These findings emphasize the necessity of multidisciplinary management of vEDs genetic testing, and the adaptation of psychological support to each gender's coping mechanism.

P01.108

Natural course of pregnancy and delivery in vascular Ehlers-Danlos syndrome: a retrospective study of 37 patients and 81 pregnancies.

M. Frank[1], *L. Golmard*[2], *A. Cordier*[3], *J. Albuisson*[2,4], *J. Mazzella*[2], *H. Plauchu*[5], *P. Khau Van Kien*[6], *E. Messas*[1,4], *A. Benachi*[3], *X. Jeunemaître*[1,2,4];
[1]*National Referral Centre for Rare Vascular Diseases, HEGP, APHP, Paris, France,* [2]*Department of Genetics, HEGP, APHP, Paris, France,* [3]*Department of Obstetrics, Hôpital A. Béclère, APHP, Clamart, France,* [4]*University Paris Descartes, Paris, France,* [5]*Department of Genetics, Hôpital Hôtel-Dieu,, Lyon, France,* [6]*Clinical Cytology and Cytogenetic Laboratory, CHU Nîmes, Nîmes, France.*

Background: Pregnancy in vascular Ehlers-Danlos syndrome (vEDS) is at high risk of maternal death. There is still limited data however on the natural course of pregnancy and the peri-partum period in the course of vEDS.
Objective: To assess obstetrical events in genetically proven vEDS patients followed in a single French referral centre.
Methods: vEDS patients with a history of pregnancy were interviewed and standardized data on number and course of pregnancies, type of birth, anaesthesia and on events during pregnancy and the peri-partum period were collected.
Results: A total of 37 patients with at least one pregnancy were included in the study. Eighty pregnancies dividing into 57 life-born infants, 2 stillborn, 12 spontaneous and 1 therapeutic abortions, 7 voluntary terminations and 1 ectopic pregnancy, were identified. Median age at delivery and at molecular diagnosis was 27[24-30] and 38[29-44] years, respectively. Diagnosis was known in 9(24%) patients at the time of delivery. One fatal and 1(1.7%) non-fatal arterial event occurred. Non arterial, vEDS-related complications (colon (1), bladder (1), uterine (2) and mitral papillary muscle (1) ruptures) occurred in 6(10.2%) deliveries. Course of pregnancy was marked by an increase in prevalence of premature rupture of membranes (20%) and preterm labour (37%). Vaginal deliveries (61%) were associated with high-grade perineal tears (50%), and caesarean-sections with severe haemorrhages (29%; p=0.003). Epidural anaesthesia (63%) when performed remained uneventful.
Conclusion: Pregnancy and the post-partum period in vEDS patients are not only marked by maternal death, but also by severe maternal morbidity, regardless of type of delivery.

Exome sequencing in a family presenting with an unclassified autosomal-recessive childhood vasculitis/stroke syndrome

E. Tilch[1], *B. Schormair*[1,2], *I. Voth*[2], *T. Wieland*[1], *E. Graf*[3], *J. U. Walther*[3], *T. M. Strom*[1,4], *T. Meitinger*[1,4], *J. Winkelmann*[1,4,2];
[1]*Institute of Human Genetics, Helmholtz Zentrum München, Neuherberg, Germany,* [2]*Department of Neurology, Klinikum rechts der Isar, Technische Universität München, Munich, Germany,* [3]*Kinderklinik und Kinderpoliklinik im Dr. v. Haunerschen Kinderspital, Ludwig-Maximilians-Universitaet Muenchen, Munich, Germany,* [4]*Institute of Human Genetics, Technische Universität München, Munich, Germany.*

We present a family from Southern Germany with an autosomal-recessive vasculitis of unknown aetiology resulting in multiple strokes with onset at childhood as the cardinal symptom. The index case had recurrent ischemias at the age of two and nine years, accompanied by fever and skin alterations. Two brothers and one sister are also affected to varying degrees of severity, whereas one sister as well as both parents don't show any symptoms. Known causes of early-onset stroke/vasculitides were excluded based on extensive clinical evaluation and laboratory tests. We performed exome sequencing in the index case using Agilent SureSelect AllExome-Kit for enrichment and Illumina 100bp-paired-end-reads for sequencing. A total of 10.8Gb of sequence were generated with 92% of the target sequence covered ≥20x. For candidate variant identification, we analysed homozygous and compound heterozygous missense, nonsense, splice-site, stoploss and frameshift variants. We excluded variants present in dbSNP135, the 1000genomes data, the ESP dataset, and an in-house exome-database with MAF>2%. Thereby, we aimed to investigate for both private and combinations of private and rare variants with putative disease-causing compound heterozygous state. We found no private or rare (MAF<2%) variants in known stroke or vasculitis risk genes. Our approach identified 24 genes with variants which were tested for co-segregation in the family. Top candidates are *ZNF259*, possibly affecting Lp-PLA_2-levels and thus vascular inflammation, as well as *CECR1*, encoding an adenosine-deaminase-related growth factor that stimulates macrophage proliferation. Additional cases with a similar phenotype are needed in order to confirm the true causal variants in this family.

P01.110

Retinopathy in HbSS and HbSC genotypes from sickle cell disease and relationship with the -308G/A polymorphism in the TNFA gene

L. S. Torres[1], *E. Belini-Junior*[1], *J. V. Okumura*[1], *W. M. Barberino*[1], *R. G. Oliveira*[1], *V. U. Teixeira*[1], *D. G. H. Silva*[1], *C. L. C. Lobo*[2], ***C. R. Bonini-Domingos***[1];
[1]*UNESP - Sao Paulo State University, Sao Jose do Rio Preto, Brazil,* [2]*HEMORIO - Institute of Hematology Arthur de Siqueira Cavalcanti, Rio de Janeiro, Brazil.*

Sickle cell disease (SCD) is among the most common genetic complications in the world. The more frequents genotypes are homozygous (HbSS) and double heterozygous HbSC. Ocular manifestations are long term complications of the SCD and mainly affect the SC individual, due to increased blood viscosity, besides possible inflammatory role in this process. The aim of this study was to determine the occurrence of retinopathy in HbSS and HbSC Brazilians patients and to relate this clinical event with the polymorphism -308G/A in the gene encoding pro-inflammatory protein TNF-α (tumor necrosis factor-alpha). We evaluated 303 SCD patients from Brazilian southeast region. The genotypes for the SCD were confirmed by classical tests and molecular analysis. The -308G/A (*TNFA*) polymorphism was performed by PCR-RFLP. Statistical analysis was conducted by the *Chi*-Square and Odds *Ratio* (OR) tests. 263 samples corresponded to HbSS patients and 40 to HbSC. The retinopathies occurrence was higher in HbSC patients, with 33.3% against 5.2% in HbSS group (p<0.05). The HbSC genotype was associated with retinopathy risk (OR=6.4;2.6≤CI95%≤15.9). The allele A (-308G/A-*TNFA*) was more frequent in patients with retinopathy in both groups: HbSS (10.71% against 3.38%; p=0.02) and HbSC (40.0% against 22.8%; p=0.4). Risk factor of the allele A (-308G/A-*TNFA*) in the retinopathy in HbSS group was OR=3.43 (1.1≤CI95%≤10.6). These results confirm the prevalence of ocular manifestations in HbSC patients and suggest some effect of allele A (-308G/A-*TNFA*) in the retinopathy process, probably due its elevated ability to increase cell adhesion through the recruitment of inflammatory modulators, contributing to vaso-occlusive events.

P01.111

Maternal mortality in Vascular Ehlers-Danlos Syndrome patients : retrospective analysis of 40 french families

J. Mazzella, *D. Molière, E. Messas, T. Mirault, X. Jeunemaitre, M. Frank; Hôpital Européen Georges Pompidou, Paris, France.*

Background : Vascular Ehlers-Danlos syndrome (vEDS) is a rare genetic disease caused by mutations in the *COL3A1* gene. Affected patients show increased vascular, intestinal and uterine fragility. Pregnancies are considered at high risk for vEDS patients, but there is a paucity of data on the prevalence of mortality in this population.
Objective : To assess maternal mortality (MM) in vEDS patients followed in a single French referral center.
Methods : We retrospectively reviewed medical charts and pedigrees of all vEDS patients referred to our centre. Index-cases and their female ascendants (mothers and grand-mothers) were classified as carriers, likely or unlikely transmitters according to their family pedigree. Live births in pedigrees of carriers and likely transmitters were selected for mortality calculation. Neomutations (both parents negative for *COL3A1* mutation) were excluded from analysis.
Results : A total of 85 families were identified of which 45 were neomutations. The remaining 40 vEDS families were eligible for analysis. Pedigrees of n=35 index-cases and female ascendants in these families showed 6 genetically confirmed vEDS cases and 32 likely transmitters. All these women gave birth to 116 live-born children. Maternal death occurred in n=9 parturients. Causes of death were either intra-abdominal arterial rupture (n=6), either uterine rupture (n=3). Medium age at death was 30.9 years ± 4.0 years. Maternal mortality rate was estimated about 7.3 %.
Conclusion : These findings confirm previous maternal mortality estimations in vEDS. However, due to specific obstetrical protective measures, a possible effect of the latter could not be measured.

P01.112

The clinical and molecular spectrum of D4ST1-deficient Ehlers-Danlos Syndrome

D. M. Syx[1], *S. Symoens*[1], *M. C. Maiburg*[2], *I. Van de Laar*[3], *J. Morton*[4], *A. De Paepe*[1], *F. Malfait*[1];
[1]*Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium,* [2]*Department of Medical Genetics, Utrecht, Netherlands,* [3]*Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands,* [4]*Clinical Genetics Unit, Birmingham Women's Hospital, Birmingham, United Kingdom.*

Recently, we described Ehlers-Danlos syndrome (EDS), musculocontractural type (former EDS-type-VIB), an autosomal recessive (AR) EDS-subtype caused by loss-of-function mutations in *CHST14*, encoding dermatan-4-sulfotransferase-1 (D4ST1). D4ST1 catalyzes 4-O-sulfation of the glycosaminoglycan dermatan-sulfate (DS), which is covalently linked to proteoglycans. Loss of D4ST1-activity results in the replacement of DS by chondroitin-sulfate on the decorin proteoglycan and leads to impaired collagen fibril assembly.
CHST14-defects have previously been associated with the 'adducted-thumb-clubfoot-syndrome' and the EDS-Kosho-type. Based on their clinical and molecular overlap, these entities likely represent one phenotypic continuum, referred to as 'D4ST1-deficient EDS'. Here, we present a comprehensive phenotypic characterization and novel homozygous *CHST14*-mutations in three new D4ST1-deficient EDS patients to highlight the severe and pleiotropic presentation of the disorder and to further document its molecular basis. Characteristic clinical manifestations are the craniofacial abnormalities, severe skin fragility with dystrophic scarring, and easy bruising, excessive palmar wrinkling, tapered fingers, congenital joint contractures with distal joint hyperlaxity, clubfeet, and early-onset eye abnormalities, including glaucoma, cataract and retinal detachment.
Despite clinical overlap with several other recessive EDS subtypes such as EDS-type-VIA, spondylocheirodysplastic EDS, FKBP14-deficient EDS, and progeroid EDS, the condition can be recognized by its characteristic craniofacial features, congenital joint contractures with adducted thumb and clubfeet, and severe gastrointestinal and urogenital manifestations. The mutation spectrum includes homozygous and/or compound heterozygous nonsense, missense and frameshift mutations, all causing loss of D4ST1 function. By linking EDS to genetic defects in proteoglycan synthesis, this disorder further highlights the broad genetic heterogeneity of the EDS spectrum.

Oculocutaneous albinism (OCA) is an autosomal recessive disease characterized by hypopigmentation of the skin, hair and eyes. Molecular analysis allows to classify patients, depending on the gene that is mutated, into OCA1 (*TYR* gene), OCA2 (formerly called P gene), OCA3 (*TYRP1*) and OCA4 (*SLC45A2*). Deletions and duplications are investigated using ultra-high resolution array-CGH, in which the 4 genes are covered at a density of 1 probe/102bp on average. We report two patients with a complex rearrangement. Array-CGH analysis indicated the presence of two heterozygous deletions restricted to introns 2 and 20 respectively, the intervening segment being present in two copies. Both deletions were inherited from her mother, thus indicating that both deletions were on the same allele. Patient 2 was heterozygous for the same deletions of introns 2 and 20 as patient 1. Remarkably, the 5' breakpoint of the intron 2 deletion and the 3' breakpoint of the intron 20 deletion seemed to be at the same position as the breakpoints of an intron 2-20 deletion that previously identified in three patients of polish origin. The same haplotype as that associated with the intron 2-20 deletion in the polish patients was observed. A PCR-sequence analysis performed with primers located on each side of the intron 2-20 deletion confirmed that patients 1 and 2 indeed harbored the "polish" deletion. FISH analysis showed that the intervening segment was inserted near the *OCA2* gene. High throughput sequencing of the entire 15q11-13 region revealed a complex rearrangement in *OCA2* gene.

KRT74 mutation associated with autosomal recessive hair-nail ectodermal dysplasia

D. Raykova[1], *J. Klar*[1], *A. Azhar*[2], *M. Wajid*[2], *T. Naeem Khan*[2], *S. M. Baig*[2], *N. Dahl*[1];
[1]*Department of Immunonology, Genetics and Pathology, Science for Life Laboratory at Uppsala University, Biomedical Centre, Uppsala, Sweden,* [2]*Human Molecular Genetics Laboratory, Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan.*

Pure hair and nail ectodermal dysplasia (PHNED) comprises a heterogeneous group of rare heritable disorders characterized by thin and brittle hair, hypotrichosis, onychodystrophy and micronychia. PHNED has previously been associated with mutations in *KRTHB5* and *HOXC13* on chromosome 12p11.1-q14.3. We have investigated a consanguineous Pakistani family with autosomal recessive PHNED linked to the keratin gene cluster on 12p11.1 but without detectable mutations in *KRTHB5* and *HOXC13*. Exome sequencing of affected family members revealed three linked genes with missense variants that were excluded in a control population. One of these variants (c.T821C, p.Phe274Ser) is located in the *KRT74* gene expressed in hair follicles and nail matrix. The *KRT74* variant segregates in a homozygous state in all affected family members, whereas all heterozygous carriers have normal hair and nails. Heterozygous *KRT74* mutations have previously been associated with autosomal dominant hypotrichosis simplex and wooly hair (HSWH). Our results suggest for the first time that homozygosity for a *KRT74* missense mutation causes autosomal recessive PHNED. These findings expand the phenotypic spectrum associated with *KRT74* mutations and imply that autosomal recessive PHNED and autosomal dominant HSWH are allelic conditions.

Restrictive dermopathy (RD) is a rare and extremely severe congenital genodermatosis, characterized by a tight rigid skin with erosions at flexure sites, multiple joint contractures, low bone density and pulmonary insufficiency generally leading to death in the perinatal period. RD is caused in most patients by compound heterozygous or homozygous *ZMPSTE24* null mutations. This gene encodes a metalloprotease specifically involved in lamin A post-translational processing. Here, we report 7 novel *ZMPSTE24* mutations, identified in classical RD or Mandibulo-acral Dysplasia (MAD) affected patients. We also report 9 new families with one or two affected children carrying the common, homozygous thymine insertion in exon 9 and demonstrate the lack of a founder effect. Additionally, we describe several new *ZMPSTE24* variants identified in unaffected controls or in patients affected with non-classical progeroid syndromes. This mutation update includes a comprehensive search of the literature on previously described *ZMPSTE24* mutations and associated phenotypes. Moreover, pathophysiological mechanisms underlying RD and other premature aging syndromes linked to *ZMPSTE24* are deeply discussed, confirming a general rule: RD mutations lead to complete loss-of-function of ZMPSTE24, whereas other less severe phenotypes are associated with at least one haploinsufficient allele.

The class II cytokines and psoriasis: a case-control study and meta-analysis

E. Galimova[1,2,3], *V. Akhmetova*[1], *B. Latipov*[4], *K. Kingo*[5,6], *R. Rätsep*[3,6], *T. Traks*[5,6], *S. Kõks*[3,6], *E. Khusnutdinova*[1,2];

[1]Institute of Biochemistry ang Genetics, Ufa Scientific Center of Russian Academy of Sciences, Ufa, Russian Federation, [2]Department of Genetics and Fundamental Medicine, Bashkir State University, Ufa, Russian Federation, [3]Department of Physiology, University of Tartu, Tartu, Estonia, [4]Republican Dispensary of Dermatology and Venerology, Ufa, Russian Federation, [5]Department of Dermatology and Venerology, University of Tartu, Tartu, Estonia, [6]Centre of Molecular and Clinical Medicine, University of Tartu, Tartu, Estonia.

Background: The molecular basis of pathogenesis of psoriasis remains unclear, but one unifying
hypothesis of disease aetiology is the cytokine network model. The class II cytokines (CF2) and their receptors (CRF2) are all involved in the inflammatory processes and single nucleotide polymorphisms (SNPs) in respective genes have been associated with psoriasis in a previous study of the Estonian population.
Methods: DNA was obtained from 395 psoriasis patients of two ethnic groups from the Volga-Ural region of Russia and 476 ethnically matched controls. 47 SNPs in the loci of the CF2 genes and CRF2 were selected by SNPbrowser version 3.5. Genotyping was performed using the SNPlexTM platform.
Results: The genetic variant rs30461 previously associated in original case-control study in Estonians, was also associated in Russians (Pc = 0.008, OR = 0.44), but did not reach statistical significance in the Bashkir population. Combined meta-analysis of three populations, including 943 psoriasis patients and 812 healthy controls, showed that the IL29 rs30461 C-allele was not associated with decreased risk of psoriasis (P = 0.165, OR = 0.68). Moreover, stratification of studies by ethnicity revealed a significant association in the European cohort (P = 9.506E-006, OR = 0.53).
Conclusion: Therefore, there is no overall evidence of association between psoriasis and SNP rs30461 of the IL29 gene, but there is some evidence to suggest that an association exists in Europeans. However, this current concept should be considered as preliminary and the results need to be confirmed in future independent studies.

P01.117

Antisense mediated exon skipping gene therapy for dystrophic epidermolysis bullosa

S. Turczynski[1,2], *M. Titeux*[1,2], *L. Tonasso*[3], *A. Hovnanian*[1,2,4];

[1]INSERM U781 - Imagine Institute of Genetic Diseases, Paris, France, [2]University Paris Descartes Sorbonne Cité, Paris, France, [3]CNRS UMR5288, Toulouse, France, [4]Department of Genetics, Necker Hospital, Paris, France.

Dystrophic Epidermolysis Bullosa (DEB) is a group of genodermatoses inherited in a dominant (DDEB) or recessive (RDEB) manner, characterised by severe skin and mucosae blistering after mild trauma. DEB is caused by mutations in *COL7A1* encoding type VII collagen that assembles into anchoring fibrils to form key dermo-epidermal adhesion structures. Exon skipping relies on modulating the splicing of pre-messenger RNA to induce skipping of a mutated exon. Exons 73 and 80 of *COL7A1* are of particular interest since they carry many recurrent mutations and their excision preserves the open reading frame. We first demonstrated the dispensability of these exons in an *in vivo* xenograft model using collagen VII null RDEB cells transduced with retroviral vectors containing *COL7A1* cDNAs deleted of exon 73 or exon 80. We subsequently transfected primary RDEB keratinocytes and fibroblasts with antisense oligoribonucleotides (AONs) targeting key splicing regulatory elements of these exons, and achieved efficient skipping (up to 90%). Western blot and immunocytochemistry analyses demonstrated significant type VII collagen re-expression (up to 24%) in cells from three RDEB patients which were completely deficient in type VII collagen expression before transfection. We have now grafted RDEB skin equivalents generated from patients' cells and have injected several doses of AONs to address *in vivo* efficiency. A humanized transgenic mouse carrying only the human *COL7A1* gene will also be used for pre-clinical studies to evaluate toxicity and routes of administration. If successful, this approach would offer potential for treating RDEB patients by local or systemic delivery of AONs.

P01.118

Revertant mosaicism in the first case of recessive Epidermolysis Bullosa Simplex due to *KRT5* loss of function mutations

M. Titeux[1,2], *N. Pironon*[1,2], *E. Tron*[3], *S. Fraitag*[4], *C. Prost-Squarcioni*[5], *A. Hovnanian*[1,2,3];

[1]Inserm U781 - Institut Imagine, Paris, France, [2]University Paris Descartes - Sorbonne Cité, Paris, France, [3]Department of Genetics, Necker Hospital, Paris, France, [4]Department of Histology, Necker Hospital, Paris, France, [5]Department of Histology, Avicenne Hospital, Bobigny, France.

Epidermolysis bullosa simplex (EBS) is characterized by intra-epidermal blistering upon mild trauma. Most EBS cases are caused by dominant missense mutations in *KRT5* or *KRT14* encoding keratin 5 and keratin 14, but few cases of recessively inherited EBS due to *KRT14* mutations have been reported. In this study, we report the case of a 14 months-old girl from unrelated healthy parents, presenting with severe and extensive skin blistering at birth with partial improvement during childhood and patches of non-blistering skin. Direct sequencing of *KRT5* from blood leukocyte DNA of the proband and her parents revealed two recessive loss-of-function mutations leading to frameshift and PTC: 1) a two base-pair deletion in exon 3 inherited from the mother; 2) a T>C transition deep within intron 2 inherited from the father. The latter disrupts *KRT5* pre-mRNA splicing and leads to the inclusion of a 41 nucleotides pseudo-exon through imbalanced binding of SRp40 and hnRNPA1 splicing factors. Western blot analysis from patient keratinocytes demonstrated reduced level of full-length keratin 5 indicating that the intronic mutation is leaky, rescuing the synthesis of a small amount of wild-type protein. Splicing modulation using an antisense oligoribonucleotide targeting the mutation restored the synthesis of wild type *KRT5* mRNA and keratin 5 protein. Remarkably, direct sequencing, RT-PCR and immunohistofluorescence analyses of islands of non-blistering skin demonstrated somatic revertant mutations. This is the first reported case of recessive EBS due to *KRT5* mutations, demonstrating gene dosage effect in EBS and presenting with revertant mosaicism.

P01.119

Filaggrin mutations in Slovenian patients with atopic and contact dermatitis

M. Rijavec[1], *H. Rupnik*[2], *P. Korošec*[1];

[1]University Clinic of Respiratory and Allergic Diseases Golnik, Golnik, Slovenia, [2]Department of Dermatovenereology, University Medical Centre Ljubljana, Ljubljana, Slovenia.

Dysfunction of epidermal barrier contributes significantly to the development of common skin diseases, such as atopic dermatitis (AD), allergic contact (ACD) and chronic irritant contact dermatitis (CICD). One of the most important proteins, involved in generation and maintenance of epidermal barrier, is filaggrin, encoded by the filaggrin gene (*FLG*), located within the epidermal differentiation complex on chromosome 1q21.
Four prevalent loss-of-function mutations in the *FLG* gene (R501X, 2282del4, R2447X and S3247X) were genotyped in 241 AD, 100 ACD and 44 CICD patients and in 164 healthy controls from Slovenia.
The most frequent *FLG* mutation 2282del4, but not R501X, R2447X or S3247X, was significantly associated with greater risk for AD (OR=4.33, 95% CI: 1.26-14.96, P=0.012). Furthermore, subgroup analysis among AD patients revealed that carriers of *FLG* loss-of-function mutation were more likely to have earlier onset (<2 years: OR=8.09, 95% CI: 2.19-29.87, P=0.0006) and longer persistence of the disease (>20 years: OR=15.54, 95% CI: 4.13-58.44, P<0.0001) as well as they more often required hospitalisation (OR=12.38, 95% CI: 3.36-45.60, P<0.0001). On the other hand no association between *FLG* mutations and ACD or CICD, were found.
The *FLG* loss-of-function mutations that contribute to the impaired epithelial barrier function, increases the risk for development of AD, but not ACD or CICD, in Slovenian patients. *FLG* mutations are also a predisposing factor for a more severe AD phenotype, leading to earlier onset, longer persistence and hospitalisation. Genotyping of *FLG* mutations is helpful for identification of patients at higher risk for severe and more persistent disease.

P01.120

Mutations in *IL36RN* in patients with generalized pustular psoriasis

U. D. Hüffmeier[1], *A. Körber*[2], *R. Renner*[3], *H. Sticht*[4], *D. Wilsmann-Theis*[5], *P. Schulz*[6], *M. Sticherling*[3], *H. Traupe*[7], *R. Mössner*[8];
[1]*Human Genetics, University of Erlangen, Erlangen, Germany,* [2]*Department of Dermatology, University of Essen, Essen, Germany,* [3]*Department of Dermatology, University of Erlangen, Erlangen, Germany,* [4]*Bioinformatics in Biochemistry, University of Erlangen, Erlangen, Germany,* [5]*Deparment of Dermatology, University of Bonn, Bonn, Germany,* [6]*Department of Dermatology, Bad Bentheim, Bad Bentheim, Germany,* [7]*Department of Dermatology, University of Münster, Münster, Germany,* [8]*Department of Dermatology, University of Göttingen, Göttingen, Germany.*

GPP is a rare disorder affecting 2 of 1 million individuals in Europe. It is characterized by repeating flare-ups of pustular psoriasis and a potentially life-threatening accompanying multisystemic inflammation. Recently, missense mutations in IL36RN were identified for GPP. We screened IL36RN in 19 GPP patients and identified mutations in 7 patients: 4 homozygous for p.His32Arg, p.Pro76Leu or p.Ser113Leu (twice), and 3 patients compound heterozygous for p.Ser113Leu and either p.Arg48Trp, p.Glu94X or p.Pro76Leu. p.Glu94X as well as the 2 missense mutations p.His32Arg and p.Pro76Leu affecting highly conserved residues were novel. Molecular modeling of missense mutations revealed effects on protein stability or binding to IL-36 receptor. The newly identified mutations were not present in 190 controls. Available parents were tested as heterozygous mutations carriers. 1 further patient was heterozygous for p.S113L, while neither he nor 11 patients without IL36RN mutations had an intragenic deletion. Phenotype genotype correlation was difficult due to different mutations in few carriers. No significant difference in age of onset between noncarriers/ carriers of mutations was observed. The widely varying age of onset (1-51 y.) in 4 homozygous patients for p.Ser113Leu (2 previously published) can currently not be explained. An additional coding variant (p.Ser200Asn) in *CARD14* was identified in one of them (aoo.: 1 year) which might modify disease severity. The rate of 35.2% IL36RN mutation carriers provides further evidence that GPP is heterogeneous. As therapy with anakinra in some GPP patients is effective, revealing the molecular basis of GPP in single patients is important for therapeutic decision-making.

Hidradenitis Suppurativa / acne inversa (AI) is a chronic, inflammatory, recurrent, debilitating skin follicle disease that usually presents after puberty with painful, deep-seated, inflamed lesions in the apocrine gland-bearing areas of the body, most commonly the axillaries, inguinal, and anogenital regions. Recently, mutations of *NCSTN*, *PSEN1* and *PSENEN* genes located at 1q23.3, 19q13.12 and 14q24.2, respectively, have been reported in sporadic and familial AI patients, suggesting that these genes play an important role in AI development. Here, we report two novel mutations of *NCSTN* in two multi-generational Indian families with AI and various associated anomalies including squamous cell carcinoma. Mutation search in exons and splice junctions of above three candidate genes identified a frameshift mutation, c.687insCC (p.Cys230ProfsX31), which is predicted to terminate at codon 261 after the addition of 31 novel amino acids within exon 6 of *NCSTN*. A nonsense mutation due to a 2-nt deletion, resulting in a stop codon (L600X), within exon 16 of *NCSTN* was found in family UR-253. It is known that *NCSTN* is subunit of the γ-secretase complex, an endoprotease complex that catalyzes the intramembrane cleavage of integral membrane proteins such as Notch receptors and APP (β-amyloid precursor protein). We did not detect a pathogenic or predisposing variant in any candidate genes in another three multigenerational AI families, indicating genetic heterogeneity in AI. Identification of present novel mutations expands *NCSTN* gene mutation spectrum associated with AI phenotype. The present data supported the significance of γ-secretase dysfunction in the etiology of AI.

P01.122

IP-associated NEMO mutations as a tool to unravel the key molecular mechanisms in NF-kappaB activation

A. Pescatore[1], *E. Esposito*[1], *G. Courtois*[2], *V. Ursini*[1];
[1]*nstitute of Genetics and Biophysics "Adriano Buzzati Traverso" CNR, Naples, Italy,* [2]*nstitut de Recherches en Technologies et Sciences pour le Vivant (iRTSV), Grenoble, France.*

Mutations of the gene coding for NEMO has been shown to cause the X-linked inherited disease Incontinentia Pigmenti (IP). IP presents with skin lesions appearing at birth and evolving in four typical inflammatory stages. In addition, other neuroectodermal tissues can be affected. NEMO is the regulatory subunit of the kinase complex IKK, required for the canonical NF-kappaB activations. Further progress on the comprehension of the IP physiopathology depends also on the detailed understanding of the mechanisms of action of NEMO mutated protein in the context of IP pathology.
Starting from the NEMO screening in a large cohort of IP patients from EU we investigated the IP physiopathology by studying selected mutations in several cell lines.
We described a NUB (NEMO Ubiquitin Binding) domain mutation, A323P that we found in a patient with a severe form of IP. This substitution caused a defect in the non-degradative ubiquitination process and, consequently, drastically decreased NEMO-dependent NF-kappaB activation. Combining these evidences to the molecular study of an N-terminal missense mutation (E57K), we finally characterized the domains participating in NEMO/TRAF6 interaction, providing genetic and molecular evidences supporting the role of this physical interaction in NF-kappaB activation. More important, dissecting specific molecular interactions within the NEMO-related activity, not only as NF-kappaB regulator, could suggest new targets for the development of potentially effective therapeutic strategies.
This study is supported by the Association Incontinentia Pigmenti France (http://www.incontinentiapigmenti.fr).

In humans, inherited palmoplantar keratoderma is a complex heterogeneous group of genodermatoses clinically presenting as hyperkeratosis of the palms and soles. Genetic causes of non syndromic autosomal recessive keratoderma are not well known except for Meleda's disease. In dogs, footpad hyperkeratosis naturally segregates mainly in two breeds, Dogue de Bordeaux and Irish Terrier. The onset usually occurs in puppies of six months old or younger. Clinical signs consist of dermatological lesions affecting footpads and/or nose showing thickening with severe keratinous proliferations and fissures. These two breeds having concentrated deleterious alleles due to the drastic selection of these breeds. Pedigree analyses led us to hypothesize a monogenic recessive inheritance of the disease in each breed. The genetic causes of the disease in the two dog breeds are searched by genetic linkage and genetic association studies. We collected blood samples from 100 Dogues de Bordeaux, including 30 affected dogs and 33 Irish Terrier, including 12 affected dogs. We performed a Genome Wide Association Study in both breeds using the recently available Illumina Canine HD 170,000 SNPs array. To date, most of the genes known to be involved in human Palmoplantar Keratoderma, have been excluded by genetic linkage, allowing to hypothesize that novel genes could be discovered in the two dog breeds. These approaches, in addition to comparative genetics, bring alternative spontaneous models and also open the field for clinical trials for the benefit of dogs and humans.

P01.124

Molecular study in a patient with *Incontinentia pigmenti*

C. Cervera-Acedo[1], *J. Aguirre-Lamban*[1], *J. del Olmo López*[2], *A. Olloqui Escalona*[2], *A. Garcia-Oguiza*[3], *M. Poch-Olive*[3], *E. Dominguez-Garrido*[1];
[1]*Fundación Rioja Salud-CIBIR, Logroño, Spain,* [2]*Fundación Hospital de Calahorra, Calahorra, Spain,* [3]*Hospital San Pedro, Logroño, Spain.*

Introduction
Incontinentia pigmenti (IP) is a rare X-linked dominant genodermatosis (Xq28), lethal in the majority of affected males in utero and variably expressed in females due to lyonization phenomenon. The diagnosis of IP is based on clinical findings and molecular genetic testing of *IKBKG* (*NEMO*) gene. It consists of 10 exons and encodes a protein of 419 amino acids. Approximately 65% of affected females present a 11.7 kb deletion that removes exons 4-10 of the *NEMO* gene.
Subjects and Methods
A one and a half year old female patient, with healthy and non-consanguineous parents, was dignosed with IP by skin biopsy. The karyotype was normal, 46XX. Multiplex PCR and electrophoresis were performed to identify the common deletion. In addition, sequencing analysis of all the 10 exons was performed. The X chromosome inactivation (XCI) pattern was determined by PCR amplification at the Androgen receptor locus (HUMARA).
Results
Deletion of exons 4 to 10 was not detected. Moreover, no additional variants were found. The XCI showed a partial skewing: 16% / 84%.
Discussion
IP is a severe systemic pathology that requires multidisciplinary follow-up, particularly during the first year of life. Currently, *NEMO* is the only known gene associated with IP, and it is responsible of 73% of the cases. cDNA sequencing analysis will be analyzed. Due to the etiology is still unknown in the remaining 27%, it suggests that other genes should be further investigated.

Porphyria Cutanea Tarda (PCT): An exploratory focus group study

J. Andersen[1,2], *M. Råheim*[2], *G. A. Strandnæs*[1], *S. Sandberg*[1,2], *E. Gjengedal*[2];
[1]*Haukeland University Hospital, Bergen, Norway,* [2]*University of Bergen, Bergen, Norway.*

PCT is characterized by fragile skin with blistering on sun exposed areas, and exists in both hereditary and sporadic forms. Symptoms typically develop in late adulthood and can be triggered by iron overload, alcohol intake, estrogens and various liver diseases. Treatment consists of phlebotomy to reduce iron, or to increase urinary porphyrin excretion by administering chlorochin. The Norwegian Porphyria Centre (NAPOS) offers predictive genetic testing and counseling to at-risk family members in hereditary cases.
The aim was to explore what experiences persons with PCT have concerning symptoms, treatment, prevention and follow up. Interpretive description was used as a qualitative approach. Three focus groups were held, each consisting of seven participants, 11 women and 10 men aged between 31 and 77. Eleven participants had hereditary PCT, and all had experienced symptoms during the last five years.
Participants' symptoms varied from fragile skin to what was described as a desperate situation, with huge blisters, skin falling off and feeling as if in a "horror movie". Treatment with phlebotomy did cause rapid improvement and made the situation less dramatic. PCT was perceived as being in the blood, rather than a skin disease, and made participants contemplate if other health issues were caused by PCT, and if there were more to this disease than the specialist knew. Although most participants had not experienced relapses, they regarded PCT as a chronic disease, requiring controls and prophylactic phlebotomy for the reminder of their lives.

Frame shift mutation of the ZMPSTE24 gene in two siblings affected with restrictive dermopathy

A. Morkūnienė[1,2], *A. Matulevičienė*[1,2], *L. Ambrozaitytė*[1,2], *R. Meškienė*[1,2], *R. Meškauskas*[3], *A. Utkus*[1,2];
[1]*Centre for Medical Genetics, Vilnius University Hospital Santariškių Klinikos, Vilnius, Lithuania,* [2]*Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania,* [3]*National Centre of Pathology, Affiliate of Vilnius University Hospital Santariškių Klinikos, Vilnius, Lithuania.*

Restrictive dermopathy (RD) is a rare lethal autosomal genodermatosis. We report on 2 siblings from consecutive pregnancies affected with RD. The proband was born at 28 weeks of gestation to a 27-year-old healthy woman whose first child died due to respiratory insufficiency on his 16th day, falsely diagnosed with congenital ichthyosis by dermatologist. There were no further investigations performed for him at that time. Clinical symptoms of the first child showed the same morphology as that of the second baby. Physical examination of the proband showed extensive areas of tight, shiny, translucent skin with multiple fissures on the neck and shoulders and prominent cutaneous vessels. Face showed the characteristic dysmorphic features: hypertelorism, antimongoloid slant, sparsed eyelashes, small pinched nose, micrognathia, mouth O-shaped, multiple joint contractures. The patient died on 23rd day after birth due to pulmocardial insufficiency.
Skin biopsy microscopic examinations revealed evenly thickened epidermis, hypergranulosis with large keratohyalin grains and decrease of the elastic fibers in the dermis, undeveloped sweat glands.
The DNA of the proband and his parents were extracted from the venous peripheral blood samples using phenol-chlorophorm DNA extraction method. The sibling DNA was extracted from dried blood spot sample (Guthrie card) using the InstaGene™ Matrix (BIO-RAD Laboratories, Inc., USA). Amplification using specific primers for 10 exons of the *ZMPSTE24* gene was performed for all samples.
Homozygous frame shift mutation c.50delA (p.[Lys17Serfs*21];[Lys17Serfs *21]) was identified in exon 1 of the *ZMPSTE24* gene for both affected children. The parents genotypes were heterozygous for this mutation.

[1]*Kariminejad Najmabadi Pathology and Genetics Center, Tehran, Islamic Republic of Iran,* [2]*Azad University Medical Branch,Tehran, Iran, Tehran, Islamic Republic of*

Iran, [3]Mehrgan Genetic Center, Sari, Iran, Tehran, Islamic Republic of Iran, [4]4- Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium, Ghent, Belgium, [5]5- Department of Biomedical Sciences, University of Modena and Reggio Emilia, Modena, Italy, Modena, Italy, [6] Department of Ophthalmogenetics, The Netherlands Institute for Neuroscience (NIN), an institute of the Royal Netherlands Academy of Arts and Sciences (KNAW), Amsterdam, NL, Amsterdam, Netherlands, [7]6- Department of Ophthalmogenetics, The Netherlands Institute for Neuroscience (NIN), an institute of the Royal Netherlands Academy of Arts and Sciences (KNAW),, Amsterdam, Netherlands, [8]7- Department of Clinical Genetics, Academic Medical Centre, University of Amsterdam, Amsterdam, Netherlands, [9]8- Department of Ophthalmology, Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [10]9- Department of Pediatrics, AcademicMedicalCenter, University of Amsterdam, Amsterdam, Netherlands.

We describe the clinical findings and molecular results in 13 affected members of two families who had a remarkably consistent phenotype consisting of pseudoxanthoma elasticum (PXE)- like skin manifestations in neck and trunk, cutis laxa of trunk and upper limbs, and retinitis pigmentosa. They had no coagulation abnormalities.
No mutation was identified in *ABCC6* known to cause PXE. Subsequently, all 13 affected family members were found to be homozygous for the splice-site mutation c373+3G>T in the Gamma-Glutamyl carboxylase (*GGCX*) gene. Parents were heterozygous and healthy siblings were either heterozygous or had the wild-type. The two families were not known to be related, but originated from the same geographic region suggesting a founder effect.
GGCX mutations have been reported in patients with a PXE-like phenotype and cutis laxa before in patients who also had multiple Vitamin K-dependent coagulation factor deficiencies and no retinitis pigmentosa. We suggest that the present affected individuals represent a hitherto unreported phenotype associated with *GGCX* mutations, as the presence of two independent disorders co-segregating in 13 family members and not occurring in an isolated way in other family members us unlikely. Di-genic inheritance has been suggested to explain the variations in phenotype in *GGCX* mutation carriers. Consequently, the present unusual phenotype may not be explained by the GGCX mutations alone but may be influenced by variants in other genes or epigenetic and environmental factors.

Odonto-Onycho-Dermal Dysplasia/Schopf-Schulz-Passarge Syndrome spectrum: An interesting case.

M. Bedford[1], *F. Mussani*[2];
[1]*Genetics Department, North York General Hospital, Toronto, ON, Canada,* [2]*Division of Dermatology, University of Toronto, Sunnybrook Health Sciences Centre, Toronto, ON, Canada.*

We present a case of a 38-year-old female from Newfoundland with a multitude of symptoms pertaining to her hair, nails, teeth and skin. For many years, she has had slow growing, fine, brittle hair on her scalp and scarring alopecia. Since childhood, she has had dystrophic finger and toenails and previously had dental work for peg shaped teeth. Furthermore, she has always had diminished sweating and palmo-plantar keratoderma. Recently, she has been diagnosed with a melanoma in-situ and eyelid cysts. Dysmorphology exam noted a bird-like facies.
This patient's presentation is consistent with features of both Odonto-Onycho-Dermal Dysplasia (OODD) and Schopf-Schulz-Passarge syndrome (SSPS). There is considerable overlap in clinical features between the two conditions. Both types of ectodermal dysplasia are autosomal recessive and have been associated with homozygous and compound heterozygous mutations of the WNT10A gene. Our patient was found to be homozygous for the Cys107X mutation in WNT10A. This particular mutation has been reported in cases of both OODS and SSPS suggesting that features of these two conditions are part of a spectrum connected by the same gene. Basal cell and squamous cell carcinomas have been reported in SSPS. Unique to this case is the occurrence of melanoma in situ. To our knowledge this is the first case of a WNT10A gene mutation reported in the Newfoundland population.

P01.129

The transglutaminase 5 mutations are frequent among Polish patients with acral skin blistering

D. Nesteruk[1], *K. Wertheim-Tysarowska*[1], *A. Giza*[1], *J. Sota*[1], *J. Bal*[1], *C. Kowalewski*[2];
[1]*Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland,* [2]*Department of Dermatology, Medical University of Warsaw, Warsaw, Poland.*

Localized Simplex Epidermolysis Bullosa (EBS-loc., EBS Weber-Cockayne) is caused by mutations in keratins *5* and *14*. However, in 50% of patients these mutations are not found despite acral skin blistering presence. This symptom is also present in another condition - acral peeling skin syndrome (APSS) caused by mutations in a *TGM5* gene encoding transglutaminase 5. So far only 24 APSS cases have been reported worldwide and no epidemiological data for Slavic population are available.
The aim of the study was to verify the hypothesis that *TGM5* mutations occur in Polish patients with EBS-loc. clinical suspicion, no mutations in *KRT5, KRT14* and no family history of blistering disorders.
DNA from 20 unrelated probands was analyzed by direct sequencing of the *TGM5.*
The Gly113Cys mutation was detected in 55% (22/40) alleles of affected patients (9 homozygous, 4 heterozygous cases) and in 2 (2%) healthy controls (n=103). A novel mutation - c.331delG was found in three proband's alleles. Molecular studies are currently being pursued.
Our results indicate that *TGM5* mutations are common in Polish patients with the clinical suspicion of the EBS-loc., which strongly supports the idea of the *TGM5* molecular analysis incorporation into the first line diagnostic procedure in such cases. We showed for the first time that Gly113Cys mutation is common in Polish patients and we identified previously unreported recurrent mutation - c.331delG. High frequency of Gly113Cys in control population may also suggest that APSS incidence is highly underestimated in Poland.

P01.130

No mutations in the serotonin related TPH1 and HTR1B genes in patients with monogenic sclerosing bone disorders.

E. Boudin[1], *K. Jennes*[1], *F. de Freitas*[1], *D. Tegay*[2], *G. Mortier*[1,3], *W. Van Hul*[1];
[1]*University of Antwerp, Edegem, Belgium,* [2]*New York Institute of Technology College of Osteopathic Medicine (NYITCOM), Old Westbury, NY, United States,* [3]*University Hospital Antwerp, Edegem, Belgium.*

Since the identification of LRP5 as the causative gene for the osteoporosis pseudoglioma syndrome (OPPG) as well as the high bone mass (HBM) phenotype, LRP5 and the Wnt/β-catenin signaling have been extensively studied for their role in the differentiation, proliferation and apoptosis of osteoblasts and osteocytes. However, more recently the direct effect of LRP5 on osteoblasts and bone formation has been questioned. Gene expression studies showed that mice lacking lrp5 have increased expression of tryptophan hydroxylase 1 (tph1), the rate limiting enzyme for the production of serotonin in the gut. Furthermore, mice lacking either tph1 or htr1B, the receptor for serotonin on the osteoblasts, were reported to have an increased bone mass due to increased bone formation. This led to the hypothesis that LRP5 influences bone formation indirectly by regulating the expression of thp1 and the production of serotonin in the gut. Based on these data we decided to evaluate the role of TPH1 and HTR1B in the development of craniotubular hyperostoses, a group of monogenic sclerosing bone dysplasias. Using Sanger sequencing, we screened the coding regions of both selected genes in 53 patients with a form of craniotubular hyperostosis which lack a mutation in the known causative genes LRP5, LRP4 and SOST. We found several common and rare coding variants in both studied genes. However, we could not identify disease-causing variants in neither of the tested genes. Therefore, we cannot provide support for an important function of serotonin in the pathogenesis of sclerosing bone dysplasias.

ZNF750 is expressed in differentiated keratinocytes and regulates epidermal late differentiation genes

I. Cohen[1,2], *R. Y. Birnbaum*[3,4], *K. Leibson*[1,2], *R. Taube*[2], *S. Sivan*[1,2], *O. S. Birk*[1,2,5];
[1]*The Morris Kahn Laboratory of Human Genetics, National Institute for Biotechnology in the Negev, Ben Gurion University, Beer-Sheva, Israel,* [2]*Department of Molecular Genetics and Virology, Ben-Gurion University, Beer-Sheva, Israel,* [3]*Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA, United States,* [4]*Institute for Human Genetics, University of California San Francisco, San Francisco, CA, United States,* [5]*Genetics Institute, Soroka Medical Center, Beer-Sheva, Israel.*

Disrupted skin barrier due to altered keratinocyte differentiation is common in pathologic conditions such as atopic dermatitis, ichthyosis and psoriasis. However, the molecular cascades governing keratinocyte terminal differentiation are not fully understood. We have previously demonstrated that a

dominant mutation in ZNF750 leads to a clinical phenotype reminiscent of psoriasis and seborrheic dermatitis. Here we show that ZNF750 is a nuclear effector that is strongly activated in and essential for keratinocyte terminal differentiation. ZNF750 was specifically expressed in the epidermal suprabasal layers and its expression was augmented during differentiation, both in human skin and in-vitro, peaking in the granular layer. Silencing of ZNF750 in differentiated HaCaT keratinocytes led to sustained proliferation, as well as diminished apoptosis. Genome-wide expression analysis of keratinocytes in which ZNF750 expression was silenced, showed markedly reduced expression of epidermal late differentiation genes, including gene subsets of epidermal differentiation complex and skin barrier formation such as FLG, LOR, SPINK5, ALOX12B and DSG1, known to be mutated in various human skin diseases. Furthermore, overexpression of ZNF750 in undifferentiated keratinocytes induced terminal differentiation genes. Thus, ZNF750 is a regulator of keratinocyte terminal differentiation and with its downstream targets can serve in future elucidation of therapeutics for common diseases of skin barrier.

P01.132

Deciphering the genetics of inherited zinc deficiencies

S. Küry[1], *S. Schmitt*[1], *E. Blouin*[2], *S. Bezieau*[1];
[1]*CHU Nantes, Service de Génétique Médicale, Nantes, France,* [2]*Laboratoire Labcatal, MontRouge, France.*

Background: Acrodermatitis enteropathica (AE; MIM #201100) is a rare and severe autosomal recessive zinc deficiency disorder, characterized by acral and periorificial dermatitis, alopecia and diarrhea. In 2002, we and others identified *SLC39A4* as the AE-causing gene, the mutation of which induced a defective intestinal zinc transport. The routine testing of *SLC39A4* which we proposed in our laboratory since then showed that only 43% of patients with a clinical picture suggestive of AE presented clearly pathogenic anomalies in *SLC39A4*.
Purpose: Our goal was to determine the genetic cause of the cases unlinked to *SLC39A4*.
Method: 76 patients with a severe zinc deficiency were included: 70 with no identified *SLC39A4* mutation, seven heterozygous for a deleterious *SLC39A4* variant, and two not screened yet by the routine testing of *SLC39A4*. A custom next-generation sequencing approach was used which targeted 50 genes directly involved in zinc homeostasis.
Results: A still preliminary analysis showed that ten cases could be related to mutations in *SLC39A4*. At least 12 patients were found heterozygous carriers of a very likely pathogenic variant in other genes of zinc homeostasis, and a differential diagnosis could be established for two patients.
Conclusions: We confirm *SLC39A4* as the main causative gene of inherited zinc deficiency. Furthermore, we highlighted several genes potentially responsible for rarer forms of zinc deficiency, which could contribute to extend our knowledge on zinc physiology. As it turns out, a whole exome sequencing approach could be followed to identify new candidate genes in still unexplained AE-like cases.

P01.133

A milder phenotype of acrodysostosis-2 due to a deletion of the proximal part of the PDE4D gene?

P. Lakeman[1], *L. C. Knegt*[1], *V. Cormier-Daire*[2], *R. C. M. Hennekam*[1,3];
[1]*Academic Medical Center, Department of Clinical Genetics, Amsterdam, Netherlands,* [2]*Département de Génétique Médicale, Université Paris Descartes, Hôpital Necker Enfants Malades., Paris, France,* [3]*Academic Medical Center, Department of Pediatrics., Amsterdam, Netherlands.*

Background: Acrodysostosis-2 (#MIM 614613) is a rare autosomal dominant skeletal dysplasia characterized by short stature, severe brachydactyly with cone-shaped epiphyses, midface and nasal hypoplasia and spinal stenosis. Many patients have (moderate) intellectual disability, some have hormone resistance (e.g. congenital hypothyroidism). In 2012, Lee *et al*. and Michot *et al*. both identified *de novo* heterozygous missense mutations in the phosphodiesterase 4D, *PDE4D* gene (5q12)(#MIM 600129), which is involved in the cyclic AMP metabolism. All mutations were absent in controls and were predicted to be pathogenic. Functional studies were not performed.
Case: a 43 year-old female patient presented with a mild intellectual disability, autism-like behaviour and depression, congenital hypothyroidism, short hands and feet (but not too short, resembling most brachydactyly type D), pectus excavatum, mild scoliosis, short stature (-1.5SD), strabismus and carpal tunnel syndrome. Childhood pictures show underdevelopment of the middle one third of the face (no longer visible now due to facial surgery). She was found to have a *de novo* 5q12.1 deletion of 64 kb (hg18: 59783994-59848643) of which the proximal breakpoint is within *PDE4D* (promoter region and first exons).
Discussion: this is, as far as we know, the first non-missense *PDE4D* mutation identified. The deletion is expected to result in decreased *PDE4D* functioning. No functional studies were performed to explain the milder skeletal phenotype. Possibly, *PDE4D* missense mutations result in a dominant negative effect on protein analysis.
Conclusion: We present a relatively mild skeletal phenotype of acrodysostosis-2 due to a *de novo* deletion of the proximal part of *PDE4D*.

P01.134

Genetic and functional studies on Hungarian families with Brooke-Spiegler Syndrome

N. Nagy[1,2,3], *N. Rajan*[4], *K. Farkas*[2], *L. Kemeny*[3,2], ***M. Széll***[1,2];
[1]*University of Szeged, Dept of Medical Genetics, Szeged, Hungary,* [2]*Dermatological Research Group of the Hungarian Academy of Sciences, Szeged, Hungary,* [3]*University of Szeged, Dept of Dermatology and Allergology, Szeged, Hungary,* [4]*University of Newcastle upon Tyne, Institute of Human Genetics, Newcastle upon Tyne, United Kingdom.*

Brooke-Spiegler syndrome (BSS; OMIM 605041) is an autosomal dominant condition characterized by the development of skin appendage tumors, such as cylindromas, trichoepitheliomas and spiradenomas. BSS develops due to mutations in the tumor suppressor gene, CYLD. In this study we aimed to perform genetic and functional studies on Hungarian BSS families. Genetic screening of the CYLD gene identified a novel heterozygous missense mutation (c.2613C>G; p.His871Gln) in a Hungarian BSS pedigree located in Szeged. Functional studies on the novel missense mutation demonstrated, that the CYLD-interactor NEMO protein immunoprecipitated from fibroblasts carrying the mutation is more ubiquitinated than the one immunoprecipitated from control cells. Since NEMO is a well-known negative regulator of the NF-κB signaling pathway, we hypothesize that this novel missense mutation of the CYLD gene might influence the NF-κB signaling pathway. In another family screening we identified a recurrent heterozygous nonsense mutation (c.2806C>T, p.Arg936X) in a BSS family located in the region of Szekszárd. The same recurrent nonsense mutation was identified in an Anglo-Saxon pedigree in the UK (region of Newcastle). Haplotype analysis of the Hungarian and Anglo-Saxon BSS pedigrees carrying the same nonsense mutation revealed independent mutation events in the background of the disease. Our results suggest that the position of the identified recurrent nonsense mutation is a mutational hotspot on the gene.
The genetic screening of BSS pedigrees may identify the causative mutation on the CYLD gene thus we can offer presymptomatic screening and prenatal diagnosis, which may have a huge impact on family planning.

P01.135

Kallikrein-related peptidase 5 transgenic mice recapitulate cutaneous and systemic hallmarks of Netherton syndrome, supporting a central role of this protease in the disease

L. Furio[1,2], *S. de Veer*[1,2], *C. Deraison*[2], *A. Briot*[2], *C. Bonnart*[2], *A. Robin*[2], *A. Hovnanian*[1,2,3];
[1]*University Paris Descartes Sorbonne Cite, Paris, France,* [2]*INSERM U781 and Imagine Institute of Genetic Diseases, Paris, France,* [3]*Department of Genetics, Necker hospital, Paris, France.*

Netherton syndrome (NS) is a severe, autosomal recessive ichthyosiform dermatosis caused by mutations of the *SPINK5*-encoded lymphoepithelial Kazal-type-related inhibitor (LEKTI). Complementary studies in humans and mice demonstrate the complexity of NS pathophysiology, which involves abnormal desquamation and constitutive activation of pro-inflammatory and pro-allergic pathways. Although several proteases (kallikrein-related peptidase (KLK) 5, KLK7 and elastase 2) are overactive following absence of LEKTI, the known functions of KLK5 suggest it is central to the NS phenotype. To explore the role of KLK5 in NS, we have developed KLK5 transgenic mice (TgKLK5) whereby human KLK5 is expressed under the control of the involucrin promoter. KLK5 immunostaining demonstrated high transgene expression in the granular layer of TgKLK5 epidermis. Increased proteolytic activity was detected by zymography, both for KLK5 and for two proteases it is proposed to activate, KLK7 and elastase 2. Like in NS, TgKLK5 mice show a dramatic skin barrier defect with extensive scaling, accelerated filaggrin

processing and increased transepidermal water loss. The stratum corneum was also detached from the underlying epidermis through degradation of desmosomes. Additionally, TgKLK5 mice displayed hallmarks of cutaneous inflammation and allergy including high expression of IL-1β, TNF-α and the pro-Th2 cytokine TSLP and infiltration of mast cells and eosinophils, overtime leading to development of skin lesions due to persistent scratching. Effects of inflammation extended to the systemic level with high serum IgE and TSLP levels. As KLK5 overexpression is sufficient to replicate NS, these findings establish KLK5 as the key initiator of the biological cascade underpinning the disease.

P01.136

Genetic mosaicism associated with early Gorlin syndrome

E. Bueno Martínez[1,2], *A. Torrelo*[3], *Á. Hernández Martín*[3], *I. Palacios Álvarez*[4], *L. López Almeida*[1], *I. Rivera*[3], *R. González Sarmiento*[1,2];
[1]*Unidad de Medicina Molecular. Facultad de Medicina. Universidad de Salamanca, Salamanca, Spain,* [2]*Instituto de Investigación Biomédica de Salamanca IBSAL, Salamanca, Spain,* [3]*Hospital Niño Jesús, Madrid, Spain,* [4]*Hospital universitario de Salamanca, Salamanca, Spain.*

A 12 year old patient with multiple papular and nodular skin lesions since birth, all of them located on the right side of her body, is presented. She has unilateral, segmentally arranged basaloid skin tumors, ipsilateral, palmoplantar pits of rather large size being distributed along Blaschko's lines and an ipsilateral odontogenic keratocyst. In addition, she presents a family history of Gorlin Syndrome since her father suffers from this disease.
A molecular study of PTCH1 gene, which is associated with Gorlin syndrome, was performed by PCR and sequencing using patient's DNA extracted from peripheral blood and DNA extracted from biopsies of healthy and affected skin. In all cases was detected the c.3062A> G; p.Y1021C mutation. Furthermore, the presence of a second novel mutation (c.543_549delGGCACTC; p.S181SfsX36) that produces a stop codon and generates a truncated protein was detected only in the DNA obtained from the affected skin. A family study showed up that the father only had the mutation c.3062A> G; p.Y1021C.

Sample	Result
Peripheral blood DNA	c.3062A>G p.Y1021C
Healthy skin biopsy DNA	c.3062A>G p.Y1021C
Affected skin biopsy DNA	c.3062A>G p.Y1021C c.543_549delGGCACTC p.S181SfsX36

We conclude that c.3062A> G; p.Y1021C mutation could be the cause of familiar disease while c.543_549delGGCACTC; p.S181SfsX36 mutation could be a de novo mutation that generates a genetic mosaicism since it does not appear in every patient's cells. The presence of both mutations would make the syndrome more aggressive and be responsible of the early appearance of the disease in cells that carry both mutations.

A replication study for four keloid loci at 1q41, 3q22.3-23 and 15q21.3 in the Japanese population

A. WATANABE*, R. OGAWA, M. SASAKI, A. FUJITA, B. T. Naing, S. AKAISHI, H. HYAKUSOKU, T. SHIMADA;*
Nippon Medical School, Tokyo, Japan.

Keloid is a dermal fibroproliferative growth that results from dysfunction of the wound healing processes. A previous genome-wide association study (GWAS) reported four novel keloid-susceptibility loci at 1q41, 3q22.3-23 and 15q21.3 (Nakashima M, *et al.* Nature Genet. 2010;42,768-772). Here, we investigated the association of these loci with keloid by using an independent Japanese sample set. We performed case-control association analysis using 204 patients with keloid subjects in Nippon Medical School Hospital. The four SNPs at 1q41, 3q22.3-23 and 15q21.3 were genotyped using Small Amplicon Genotyping method. In this study, the two from four loci identified by previous GWAS, rs873549 on chromosome 1 (odds ratio (OR) = 2.09) and rs8032158 located in *NEDD4* on chromosome 15 (OR= 3.02) were significantly associated in keloid compared with control. Especially, the risk for keloid development (OR= 3.55) or the scar severity scale (OR= 4.73) increased with an increasing number of risk allele in rs8032158. Individuals with two risk alleles of the two loci showed higher risk of developing keloid than those with one risk allele alone. Our findings elucidated the significance of genetic variation at these two loci in keloid in the Japanese population.

Seeking pemphigus vulgaris causative variations in the ST18 gene

E. Ben-Asher[1], *T. Olender*[1], *A. Alkelai*[1], *O. Sarig*[2], *L. Zoller*[3], *I. Goldberg*[2], *S. Baum*[4], *A. Barzilai*[4], *H. Trau*[4], *R. Bergman*[5], *E. Sprecher*[2,6], *D. Lancet*[1];
[1]*The Weizmann Institute of Science, Rehovot, Israel,* [2]*Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel,* [3]*Maccabi Health Care Services, Tel-Aviv, Israel,* [4]*Sheba Medical Center, Tel-Hashomer, Israel,* [5]*Rambam Medical Center, Haifa, Israel,* [6]*Tel-Aviv University, Tel-Aviv, Israel.*

Pemphigus vulgaris (PV) is a severe autoimmune blistering disease caused by anti-epithelial antibodies, leading to disruption of cell–cell adhesion. The disease is exceedingly rare worldwide, but shows a 40-fold higher prevalence in Jewish populations. In a previous genome-wide association study (GWAS) in a cohort of 100 PV patients, we identified a risk allele in the vicinity of the Suppression of Tumorigenicity 18 (ST18) gene that was shown to confer a 6-fold increased risk for PV in Jews. ST18 regulates apoptosis and inflammation, two processes of direct relevance to the pathogenesis of PV. ST18 was also found to be overexpressed in the skin of PV patients as compared with healthy individuals, further supporting a role for this gene in PV (Sarig et al. 2012). In an attempt to identify ST18-associated causative variants, we performed targeted next-generation sequencing of the entire ST18 gene, including nearby regulatory regions (total of 0.47Mb) in 16 affected subjects. A case-control association analysis of 789 variants, found within the sequenced region, revealed a large genomic haplotype block strongly associated with the propensity to develop PV (p-value 0.003). This haplotype has a frequency of 50% in the sequenced cohort and only 8% in 1000 genomes sequences. The block is located within an intron of the ST18 gene that harbors a lincRNA gene. A known SNP in this lincRNA that modifies its secondary structure is enriched in the PV cohort and may be implicated in regulation of ST18 expression.

Duplication of the Rubinstein-Taybi region on 16p13.3 due to suspected germline mosaicism in two adult brothers

D. Bartholdi*, F. Wenzel, K. Heinimann, S. Cichon, P. Miny;*
Medical Genetics, University Hospital Basel, Basel, Switzerland.

Duplications of chromosomal region 16p13.3 encompassing the CREBBP gene, which is mutated in Rubinstein-Taybi syndrome, have recently been shown to cause a recognizable syndrome characterized by intellectual disability of varying degree and facial dysmorphisms. Here we report two brothers aged 30-31 years carrying a 2.3 Mb duplication of the critical region of 16p13.3 detected by molecular karyotyping.
Both patients show the facial features already described in the 16p13.3 duplication syndrome including a long face, midfacial hypoplasia, pronounced ptosis and microretrognathia with a dimple. However, the dysmorphic features are more pronounced than in the younger patients described so far in the literature. Additional to the characteristic facial features the brothers also show camptodactyly of the fingers and toes and contractures of the large joints. Both display a urogenital malformation and developed scoliosis and abdominal obesity in adolescence. While one of the brothers has mild intellectual disability the other is moderately to severely disabled, with no speech and only limited ambulation. This difference in severity is not explained by additional pathogenic copy number variants.
Analysis of the parents did not reveal any evidence for somatic mosaicism of the 16p13.3. duplication or a chromosomal rearrangement, thus suggesting germline mosaicism as the underlying cause. Germline mosaicism for chromosomal rearrangements has rarely been reported, but the family described here demonstrates that it has to be considered when several siblings appear to be affected with the same condition. In addition, this report extends the phenotype of the 16p13.3 duplication into adulthood.

Refinement of genotype-phenotype correlation in 3 patients with 1q24.3q25.1 microdeletion supports the role of CENPL and DNM3 genes.

N. Chatron[1], *A. Labalme*[1], *M. Till*[1], *M. Rossi*[2], *P. Edery*[2,3], *D. Sanlaville*[1,3], *C. Schluth-Bolard*[1,3];

1q24.3q25.1 microdeletion syndrome associates prenatal onset growth deficiency, intellectual disability, facial dysmorphism and small hands and feet. A 1.9 Mb minimal critical region (chr1: 171869242-173832704, Hg 19) containing 13 genes was recently defined for this syndrome. Here we describe three new cases of 1q24.3q25.1 deletion, including the smallest deletion reported to date. Patients presented with the clinical common characteristics including small hands and feet, clinodactyly, absence of ear lobe, broad nasal bridge and moderate intellectual disability. Homogeneous growth retardation of prenatal onset was present in patients 1 and 2 whereas growth retardation appeared later in infancy in patient 3. Array CGH and FISH allowed the characterization of these deletions. Patients 1 and 2 showed a 9.2 Mb and a 3 Mb deletion respectively, both encompassing completely the minimum critical region containing DNM3 and CENPL genes. Patient 3 carried a 6 Mb deletion overlapping only the proximal 1.2 Mb of the critical region and sparing the CENPL gene. These data combined with those of the literature strongly impute CENPL, encoding centromeric protein L, in fetal growth. They also allow to specify the supposed function of other genes within the deletion: DNM3 (Dynamin3) involved in myelination could explain intellectual disability and microRNAs 214 and 199A2 may explain facial dysmorphism based on knocked-out mice experiments. By describing the smallest deletion of the locus and cutting the minimum critical region, we were able to refine the genotype/phenotype correlation for 1q24.3q25.1 deletion and propose CENPL as main candidate gene for growth deficiency in this syndrome.

The current use of microarray-based comparative genomic hybridization allowed the identification of novel cytogenetic abnormalities. Partial trisomies of the long arm of chromosome 20 are rare. Here we report on three males with a *de novo* overlapping 7.5, 9.78 and 10 Mb duplication of chromosome 20q11.2. Together with another patient previously published in the literature with overlapping 20q11 microduplication, we showed that such patients display common clinical features including striking similar dysmorphic features with metopic ridging/trigonocephaly, full eyelids, epicanthal folds, moderate developmental delay, short hands, cryptorchidism, and normal growth to mild growth retardation. The minimal critical region of the duplication to 7.5 Mb encompassing 173 genes including *ASLX1* gene (MIM612990). *ASLX1* is a human homolog of the Drosophila *asx* gene which is an homeotic gene. D*e novo* heterozygous nonsense or truncating mutations have been reported recently in patients with Borhing-Opitz syndrome (MIM605039), a severe developmental and malformation disorder.
Because of craniofacial features in common with Borhing-Opitz syndrome, in particular metopic ridging/trigonocephaly, we suggest that duplication of *ASXL1* may contribute to the phenotype. These observations suggest a novel recognizable microduplication syndrome, and reporting of additional patients with molecular characterization will allow more detailed genotype-phenotype correlations.

22q11.2DS: MLPA and FISH results

Y. Kozlova[1], *N. Shilova*[1], *M. Minzhenkova*[1], *V. Antonenko*[1], *N. Kotlukova*[2], *E. Levchenko*[3], *V. Zabnenkova*[1], *T. Zolotukhina*[1];

[1]*Federal State Budgetary Institution "Research Centre for Medical Genetics" of the Russian Academy of Medical Sciences, Moscow, Russian Federation,* [2]*Moscow Municipal Clinical Hospital №67, Perinatal cardiological Centre, Moscow, Russian Federation,* [3]*Bakoulev Scientific Center for Cardiovascular Surgery of the Russian Academy of Medical Sciences, Moscow, Russian Federation.*

Aim: MLPA-analysis was performed on the group of probands with typical phenotype previously tested for 22q11.2 microdeletion by FISH in order to confirm data, delineate deletion size and make an effort to reveal atypical distal deletions. Materials and methods: A group of 61 probands with phenotype suggestive of 22q11.2 deletion syndrome (22q11.2DS) (CHD, facial anomalies, cleft palate, hypocalcemia) was analyzed by MLPA-analysis with SALSA MLPA P250-B1 DiGeorge (MRC-Holland). All patients previously underwent standard karyotyping in order to exclude other chromosomal aberrations. FISH-analysis with TUPLE1/ARSA (Abbott, Vysis) was performed in cultured lymphocytes. 37 patients were not deleted, 24 patients were found to carry 22q11.2 deletion. DNA for MLPA-analysis was extracted from EDTA-blood samples and from samples of Carnoy's fixated lymphocytes left over from karyotyping and FISH-analysis. Results: MLPA-analysis confirmed all 24 FISH-diagnosed cases of 22q11.2 deletion: in 19 cases A-B-C deletion was revealed, four patients had A-B deletion and one patient had A deletion. In our study MLPA-test didn't reveal nor atypical deletions neither duplications in the remaining 37 patients. DNA from EDTA-blood samples, Carnoy's cell suspension and samples from both materials analyzed simultaneously showed respective results. Conclusion: MLPA-analysis is considered to be a reliable, accurate and cost-effective method with high sensitivity and specificity for 22q11.2 microdeletion detection. MLPA with DNA-samples extracted from Carnoy's cell suspension showed reliable results. Thus, this material can be used in cases when patient or EDTA-blood sample is not available, limited amounts of accessible material and in archive cases.

49,XXXXY syndrome is a rare sex chromosome aneuploidy occurring in 1:85 000-1:100 000 male births. He has to be distinguished from Klinefelter syndrome. Data on this aneuploidy in adulthood are limited, with most of the literature data based on paediatric patients.
We report a new male patient whose 49,XXXXY diagnosis was formally made at the age of 54 years. A neurologist who examined for the first time the patient for tremor ordered the karyotype analysis. So far, no medical follow-up was performed specifically for his condition. This man presented with eunuchoid body habitus, facial features with epicanthus, hypertelorism, up-slanting palpebral fissures and features of chronic hypoandrogenism with muscular weakness, sparse body hair, dry skin with abnormal healing of skin wounds. Endocrine evaluation confirmed a hypergonadotropic hypogonadism with two testes (one cryptorchid testis). Bone mineral density showed an osteoporosis. There was no cardiac defect. He had moderate intellectual deficiency with more affected verbal skills. There were no behavioural problems and he had social and occupational capabilities with adaptive functioning. A recent deep vein thrombosis was diagnosed in his left leg. Unusually, in addition to moderate deafness, he developed progressively a severe vision impairment leading to blindness.
There have been very few reports of adult individuals with 49,XXXXY syndrome and to our knowledge only one 47-year-old male patient (Akiyama et al, 2011, J Dermatol, 38: 414). This kind of report may contribute to improved management of prospective medical healthcare associated with this condition in older individuals.

4q21 deletion syndrome: involvement of *PRKG2* in short stature and new boundaries for mental retardation and speech delay.

M. Dayem-Quere, *F. Giuliano, C. Massol, V. Paquis-Flucklinger, H. Karmous-Benailly; Hôpital de l'Archet II, CHU de Nice, Nice, France.*

Patients with interstitial 4q21-q22 deletions show several characteristic features such as neonatal muscular hypotonia, small hands and feet, severe growth restriction, mental delay, severe psychomotor retardation, absent or severely delayed speech and facial dysmorphism with a broad forehead, frontal bossing, hypertelorism, short philtrum, and downturned corners of the mouth. Many cases were described in the literature, and, recently, a study analysed nine patients with overlapping *de novo* 4q21 deletions of different sizes, ranging from 3.2 Mb to 15.2 Mb (Bonnet, 2010). They defined a minimal critical interval of 1.37 Mb, containing 5 genes, *PRKG2, RASGEF1B, HNRNPD, HNRPDL* and *ENOPH1*. Two of these genes, *PRKG2* and *RASGEF1B* were considered to be the most promising candidates for growth restriction, mental retardation, and absent or severely delayed speech. We present a study on a child with a *de novo* 4q21.22 deletion, facial anomalies, developmental delay, and mental retardation. The deletion carried by our patient is the smallest described in this region. It overlaps the minimal critical region previously described thus defining new boundaries for this emergent 4q21 deletion syndrome. Unlike all previously described cases, our patient is of normal height and does not show any growth restriction. Interestingly, in his case, the *PRKG2* gene is not deleted. We thus propose *PRKG2* to be the gene responsible for the short stature of the patients when deleted, and *RASGEF1B* and *HNRNPD* as candidate genes for the mental retardation and speech delay, two features present in all described patients without exception

5q31.3 microdeletion syndrome: clinical and molecular characterization of two further cases

N. Brown[1,2], T. Burgess[1,2], R. Forbes[1,2], G. McGillivray[1,2], A. Kornberg[3,4], S. Mandelstam[3,4], ***Z. Stark[1,2];***

[1]Victorian Clinical Genetics Service, Melbourne, Australia, [2]Murdoch Children's Research Institute, Melbourne, Australia, [3]Royal Children's Hospital, Melbourne, Australia, [4]University of Melbourne Department of Paediatrics, Melbourne, Australia.

The 5q31.3 microdeletion syndrome has recently emerged as a distinct clinical entity, and we report two new patients with de novo deletions of this region, bringing the total to seven. The phenotype is characterized by marked hypotonia, apnoea, developmental delay and feeding difficulties. Both patients had abnormal movements which did not correlate with epileptiform activity on electroencephalogram (EEG). Developmental brain changes on neuroimaging consist of abnormalities predominantly affecting the white matter and frontal lobes. The 5q31.3 deleted regions overlap those of previously reported cases, and allow further refinement of the shortest region of overlap (SRO) to 101kb, including only three genes. Of these the purine-rich element binding protein A (PURA) gene has an established role in brain development, and we propose that haploinsufficiency for this gene is primarily responsible for the neurodevelopmental features observed.

6q16 deletions are associated with a Prader-Willi-Like (PWL) phenotype. A role of several candidate genes has been suggested: SIM1 for obesity and GRIK2 for behavioural problems. However, few patients have been precisely described using high resolution microarray. We report 14 new patients with de novo 6q16 deletions all characterized by oligonucleotide or SNP microarray, among them the first fetus with a complete fetal examination. Nine patients display a PWL phenotype and allow refining of the critical region for this condition. The fetus exhibits dysmorphic facial features and particular cerebellar and cerebral abnormalities with neuronal ectopia. Deletion size in living patients ranges from 2.20 to 7.84 Mb whereas the fetus carries the largest deletion (14 Mb). Genotype-phenotype correlations reveal a novel minimal critical region for PWL phenotype comprising SIM1 and MCHR2 genes. This study confirms, on the largest series reported to date, the strong association between PWL phenotype and 6q16 deletions as previously observed. The genes within the minimal critical region that we described seem to play a critical role in the phenotype. Also, we presented a detailed report of the first fetopathological examination of a fetus deleted for this region.

Aarskog-Scott syndrome: cases with clinical and molecular diagnosis

S. Avci*, B. N. Satkin, Z. Uyguner, H. Kayserili, U. Altunoglu;*

Department of Medical Genetics, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey.

Aarskog-Scott syndrome (AAS) is an X-linked disorder characterized by short stature, hypertelorism, shawl scrotum, and brachydactyly. There is wide phenotypic variability. Additional features include joint hyperextensibility, short nose, widow's peak, and inguinal hernia. While most patients do not have mental retardation, they exhibit neurobehavioral features. Carrier females are clinically diagnosed by widow's peak or short stature or by molecular testing whenever there is an affected male in the family. Prevalance of AAS is unknown, but less than 100 cases have been reported after 1970. *FGD1* gene was found responsible from X-linked AAS phenotype in 1994 by a group of researchers (Pasteris et al.). Thirty different mutations including missense, frameshift, nonsense, splice site, in-frame and gross deletions have been reported up till then in more than 40 families (HGMD, 14 December 2012).

We here present the clinical and molecular findings of four additional patients/families with Aarskog-Scott syndrome. Four different mutations in *FGD1* gene, including three novels, were identified in our study group. These novel mutations include two frameshift [(c.2034delA (p.Lys699LysfsX13), c.1815dupG (p.Thr606AspfsX28)] and one missense mutation [(c.1555C>T (p.Arg519Cys)]. The (c.1829G>A/p.R610Q) mutation has been previously described. In three families, familial inheritance was observed, while one case was isolated. In total, 14 additional AAS cases and 13 obligate female carriers were ascertained by pedigree analysis. Further clinical/molecular studies are underway. Clinical findings of affected males and carrier females will be discussed along with molecular data in view of the literature.

An Alström Syndrome case with immunodeficiency

*T. Ozdemir[1], N. Karaca[2], J. Marshall[3], R. Ozgul[4], A. Ozanturk[4], H. Ozdemir[2], G. Aksu[2], N. Kutukculer[2], S. Darcan[2], F. Ozkinay[5], **O. Cogulu**[5];*
[1]Faculty of Medicine Department of Medical Genetics, Izmir, Turkey, [2]Faculty of Medicine Department of Pediatrics, Izmir, Turkey, [3]The Jackson Laboratory 600 Main Street Bar Harbor, Maine, ME, United States, [4]Hacettepe University, Ankara, Turkey, [5]Faculty of Medicine Department of Pediatrics and Medical Genetics, Izmir, Turkey.

Alström syndrome (AS) is a very rare autosomal recessive genetic disorder characterized mainly by obesity, hearing loss, retinopathy, cardiomyopathy, recurrent pulmonary infections, progressive renal and hepatic dysfunction and endocrinological features. It is caused by mutations in the ALMS1 gene. Here we present an AS female with immunodeficiency. The proband is a 4.5-year-old female born to nonconsanguineous parents. She was first admitted to the hospital at 6 months old because of developmental delay and pulmonary infection. She had a history of multiple hospitalizations because of recurrent pulmonary infections. Throughout this period immunodeficiency, primary hypothyroidism, growth hormone deficiency were detected. Imaging analysis revealed cortical atrophy, ventricular dilatation and bitemporal lobe hypoplasia in cranial MRI; patent foramen ovale in echocardiography; hepatomegaly with hepatosteatosis in USG; ulnar hypoplasia, short upper limb, coxa valga, metaphyseal widening in distal femur and proximal tibia and Erlenmeyer flask bone deformity in both femur in X-Ray examinations; generalized osteoporosis in DEXA. Her physical examination showed generalized alopecia, blue sclera, jagged teeth, short neck, joint laxity, truncal obesity and generalized hypotonia. Her developmental milestones were delayed. Eye examination revealed pigmentary retinopathy and salt-pepper appearance. She had sensorineural hearing loss. Ankara Developmental Screening Inventory test showed 30 % delay in general, cognitive and linguistic development areas. Her karyotype was 46,XX. Molecular analysis revealed one heterozygous ALMS1 mutation (c.5969C>G p.Ser1990X). This result along with the clinical features, confirmed the clinical diagnosis of AS as it has been stated by Marshall et al. AS cases are suggested to be investigated for concomitant immunodeficiency.

Amelogeneses imperfectae (AI) are a heterogeneous group of rare diseases affecting the formation/mineralization of tooth enamel and transmitted according to various mode of inheritance (X-linked, autosomal dominant or recessive). These diseases exist either in isolation, with clinical manifestations limited to the oral cavity, or associated to other symptoms in syndromes as for example AI and cone-rod dystrophy, AI and epilepsy. Mutations in many genes coding for either enamel matrix proteins, enamel matrix degrading proteins, or proteins involved in hydroxyapatite formation and growth, and mineralization processes have been identified as being responsible for the clinical enamel phenotypes (hypoplastic, hypomineralized, hypomature) encountered. We explored the genotype and orodental and extraoral phenotype in a cohort of patients presenting recessive hypoplastic amelogenesis imperfecta and gingival hyperplasia caused by FAM20A gene mutations. DNA sequencing revealed two compound heterozygous and two homozygous FAM20A mutations in 6 affected individuals from 4 unrelated families (2 of them consanguineous) of various ethnic backgrounds. The orodental phenotype was strikingly similar with absent enamel, gingival hyperplasia but also intrapulpal calcifications, dental follicles hyperplasia, unerupted impacted teeth, root anomalies. Anatomopathology analysis of the gingiva demonstrated signs of discrete leuco-parakeratosis and minimal chronic inflammation.
Mouse teeth transcriptome data indicated that Fam20a as well as Fam20b, Fam20c were expressed as early as E14.5 cap tooth stage.

About 9 patients with ARC syndrome (Arthrogryposis-Renal dysfunction -Cholestasis syndrome): focus on prenatal findings

***J. Fabre-Teste**, L. Perrin, E. Serrano, O. Fenneteau, F. Muller, A. Verloes, C. Baumann;*
Hopital Robert Debré, Paris, France.

ARC syndrome is a severe autosomal recessive multisystem disorder including arthrogryposis, renal tubular acidosis and neonatal cholestatic jaundice. Other features variably reported are icthyosis, mild dysmorphic signs, anomalies of corpus callosum, recurrent infections, failure to thrive and grey platelets due to defect in platelet alpha-granules biogenesis. This syndrome affects newborns who usually die in the first year of life of infections or life-threatening haemorrhage due to platelet dysfunctions. Mutations in VPS33B and VIPAR genes have been reported in this syndrome.
We report on 9 patients from 5 pedigrees of various origins with this syndrome. We will particularly focus on prenatal findings. Transient intestinal hyperechogenicity and hypomobility were frequent findings in our patients. One patient presented with increased nuchal translucency. We will discuss the amniotic enzymatic profil.

Viennese "Fools Tower" Collection: Birth Defects and Malformation Syndromes in Archived Fetal Specimens

***J. Behunova**[1], B. Patzak[2], S. Kircher[1], F. Laccone[1], H. Rehder[1];*
[1]Institute of Medical Genetics, Medical University of Vienna, Vienna, Austria, [2]Pathologic-anatomical Collection in the Viennese Fools Tower of the Natural-Historical Museum, Vienna, Austria.

Background
A Pathologic-anatomical collection of Viennese Natural-Historical Museum has accumulated since 1796 a remarkable variety of exhibits, including a rich collection of birth defects. Formerly, the specifications of birth defects were only descriptive; nowadays, many of them are syndromologically classifiable.
Aim
Our aim is to closer determine the nature of developmental anomalies in some specified series of the Viennese Pathologic-anatomic Collection. This diagnostic work-up could help providing extraordinary learn-samples for health professionals dealing with birth defects/syndromes. Considering the rareness and age of this material, the work could be of a great international importance as well.
Material and Methods
Preliminary phase included an overall visual inspection of all (circa 1000) fetal/pediatric exhibits of the museum, in parallel with a key words-search in the museum´s electronic database. Some exhibits already underwent detailed objective evaluation.
Results
The first inspection allowed us to select 5 main "working groups" according to the leading type of external defect: 1. Orofacial clefts, non-midline, 2. Middle-line facial defects, 3. Disorders of extremities and skeletal dysplasias, 4. Congenital tumors, 5. Miscellaneous syndromes. The number of the selected exhibits counted circa 140. Already within this "first-look phase" we have clinically specified some developmental pathologies that we present here as the initial findings; among them e.g. Rosenak-, Piepcorn-, Roberts-, OFD2-, Delleman-, Beckwith-Wiedemann-, Smith-Lemli-Opitz-, Meckel-syndromes and others.
Conclusion/Plans
In further investigations all selected exhibits will undergo a detailed objective reevaluation and documentation, including X-ray, autopsies, histological and eventually DNA analysis to identify or confirm a suspected chromosomal, microdeletion or monogenic syndrome.

The ARHGAP24 gene is disrupted in two sisters with septate uterus

G. Thierry[1], *S. Ploteau*[2], *O. Pichon*[1], *D. Poulain*[1], *A. Briand*[1], *C. Veluppillai*[2], *P. Lopes*[2], *F. Jossic*[3], *M. Joubert*[3], *B. Isidor*[1], *C. Bénéteau*[1], *C. Le Caignec*[1];
[1]*CHU Nantes Medical genetics department, NANTES, France,* [2]*CHU Nantes Obstetrics and gynecology departments, NANTES, France,* [3]*CHU Nantes Anathomy Pathology Laboratory, NANTES, France.*

Uterine malformations, among them septate uterus, are a frequent cause of recurrent miscarriages. We report here two sisters, both presenting with septate uterus, in whom we identified an apparently balanced reciprocal translocation t(2;4)(q35;q21.3). Array CGH analysis excluded a microdeletion/microduplication at breakpoints. Breakpoints were mapped by FISH and sequenced by long-range PCR. The breakpoint in chromosome 2 occurred in a non-coding region while those in chromosome 4 disrupted the *ARHGAP24* gene in the 7th intron. This translocation revealed two potential candidate genes in 4q21 region: the *ARHGAP24* disrupted gene and the *MAPK10* gene located close to the breakpoint, which might be altered through a position effect. *ARHGAP24* is involved in the regulation of uterine contractions and thus appeared to be the best candidate explaining uterine malformations. *MAPK10* is also a good candidate since impairment in MAPK signalling was implicated in gonadal development disorders. Next, we performed qPCR and direct sequencing of *ARHGAP24* and *MAPK10* in 27 patients with isolated septate uterus. No point mutations or intragenic deletions/duplications were identified.

P02.015

New critical region for recently defined 4q21 microdeletion syndrome

O. Liaugaudiene, ***L. Cimbalistiene****, Z. Ciuladaite, J. Kasnauskiene, E. Preiksaitiene, V. Kucinskas;
Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania.*

4q21 deletions have been reported in a number of patients with characteristic features (facial dysmorphism, hypotonia, small hands and feet, short fingers, mild-severe growth delay, ID, severely delayed speech). We report on a new case of 4q21.22 microdeletion and suggest a new critical region for 4q21 microdeletion syndrome. *De novo* interstitial 724Kb deletion of 4q21.22 (83273844 - 84097897 bp, hg18) was detected by arrayCGH (105K) in a patient with considerable hypotonia, severely retarded psychomotor development and delayed speech, short stature (3-10 centile) and dysmorphic features (slant up palpebral fissures, posteriorly rotated ears, short concave nose with anteverted nostrils, short philtrum, prognathia, downturned corners of the mouth, single transverse palmar crease, small hands and feet, short toes).
Recently critical region for 4q21 microdeletion syndrome was defined by analyzing published cases and DECIPHER reports 1571 and 4539 (Bonnet et al., 2010). The overlapping region was from 82332981 to 83182488 bp with candidate genes *RASGEF1B* and *PRKG2*. Our reported deletion does not overlap with defined region. However, clinical features of our patient coincide with 4q21 microdeletion syndrome. We suggest other critical region (chr4:83273844 - 84066553) for this syndrome, shared by previously reported 4q21 deletions, DECIPHER cases 4539 and 4665, and our reported deletion. This region includes up to 10 RefSeq genes. Strong candidate genes are brain expressed *LIN54*, heterogeneous nuclear riboproteins *HNRPDL* and *HNRNPD* - regulators of cell cycle, transcription and mRNR stabilization. Further analysis of genes` candidates` function and expression is necessary for refining minimal deletion region leading to 4q21 microdeletion syndrome.

P02.016

Blepharophimosis and multiple congenital alterations in a boy with a 6p25 tetrasomy.

M. Palomares Bralo[1,2,3], *M. A. Mori*[1,2,3], *S. García-Miñaúr*[1], *J. Nevado Blanco*[1], *M. Torres Pérez-Hidalgo*[1], *A. Delicado Navarro*[1], *A. Coral Barreda*[4], *M. Crespo*[1], *V. Fernández Montaño*[1], *R. Martín Arenas*[1], *P. Lapunzina*[1];
[1]*Instituto de Genética Médica y Molecular (INGEMM) Hospital Universitario La Paz, Madrid., Madrid, Spain,* [2]*Unidad 753, Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Instituto de Salud Carlos III, Madrid, Spain,* [3]*IdiPaz. Instituto de Investigación Hospital Universitario La Paz, Madrid, Spain,* [4]*Unidad de Endocrinología, Servicio de Pediatría, Hospital Universitario La Paz, Madrid, Spain.*

We report a 6-year-old boy referred for clinical assessment because of failure to thrive, psychomotor delay, left renal agenesis and mild pulmonary stenosis. He presented with distinctive facial features: short and narrow palpebral fissures, ptosis, a bulbous nose and a small mouth.
A customized 60.000 oligonucleotide array-CGH (KaryoArray®v3.0, Agilent) revealed a partial tetrasomy of 6p25.1→6p25.3 of about 5.96 Mb. This region contains at least 5 *OMIM* genes including *FOXC1.* Subtelomeric metaphase *FISH* analysis (RH40931, Kreatech) showed hybridization on both 6p subtelomeres, but a brighter signal pattern was observed on one homologue. Interphase *FISH* with the same probe demonstrated four 6p signals. These findings are consistent with a 6p25.1→ 6p25.3 tandem triplication.
Partial trisomy of 6p25 is a chromosome abnormality characterized by low birth weight, psychomotor delay, growth retardation, congenital heart defects, and renal anomalies. Affected individuals present with craniofacial dysmorphism consisting in blepharophimosis, palpebral ptosis, dysplastic and low set ears, small and prominent chin and a bulbous nose. Partial tetrasomy of 6p25 is an extremely rare condition and up to date only one girl with a 6p25 tetrasomy has been described in the literature, interestingly showing strikingly similar facial features.
We would like to highlight the distinctive facial features associated with 6p25 tetrasomy and the need to consider 6p25 chromosome abnormalities in the differential diagnosis of individuals with blepharophimosis and psychomotor delay in addition to other more common entities such as Blepharophimosis-ptosis-epicanthus inversus syndrome (*BPES*) and Ohdo syndrome.

Microduplication of 17q22q23.2 due to a supernumerary marker chromosome in a girl with macrocephaly and global developmental delay

K. Writzl[1], *A. Veble*[1], *L. Lovrečić*[1], *T. Liehr*[2], *B. Peterlin*[1];
[1]*Institute of Medical Genetics, Ljubljana, Slovenia,* [2]*Institute of Human Genetics, Jena, Germany.*

Small supernumerary marker chromosomes (sSMC), defined as additional structurally rearranged chromosomes that cannot be identified by conventional chromosome-banding alone, are often seen in patients with developmental disorders. The risk and severity of the abnormal phenotype depends on the size of the sSMC and extent of the mosaicism. Application of genome-wide array technology enables full characterization of sSMC.
We report a 15-months old girl with sSMC derived from chromosome 17. The clinical features include global developmental delay, hypotonia, feeding problems, recurrent bronchiolitis, macrocephaly, and distinct facial features. A 47,XX,+mar karyotype was found in all examined metaphases from peripheral blood. Fluorescent in situ hybridization (FISH) studies demonstrated that sSMC derived from chromosome 17 and showed no hybridization signal for subcentromeric probes. Microarray analysis (185K array, Agilent Technologies) showed two gains of about 2Mb at band 17q11, and 10,5 Mb at band 17q22q23.3 (arr[hg18] 17q11(22,367,302-24,320,006)×3,17q22 q23.3(49,265,451-59,786,509)×3). FISH analysis using MPO probe confirmed that sSMC contains17q22 region.
The clinical data of 17q11 and 17q22q23.3 microduplication are scarce. Alvarado et al. reported 17q23.1q23.2 microduplication as a potential CNV locus for isolated clubfoot and Radio et al. described a boy with 17q23.2 microduplication who presented with intellectual disability, brain, heart and skeletal anomalies. Main candidate genes are TBX2 and TBX4. Although the present patient has a duplication of both genes, she shares neither the clubfoot nor the heart abnormalities.
In conclusion, application of genome-wide array technology can reveal unpredicted complexity of the sSMC containing non-contiguous regions and increases the knowledge of the clinical picture of interstitial microduplications.

Array-CGH analysis suggests genetic heterogeneity in Rhombencephalosynapsis

L. Pasquier[1], *F. Demurger*[1], *C. Dubourg*[2,3], *V. Dupé*[3], *B. Leheup*[4], *J. Lespinasse*[5], *P. Loget*[6], *P. Marcorelles*[7], *A. Laquerrière*[8,9], *S. Odent*[1,3], *V. David*[2,3];

[1]*Service Génétique Clinique - CHU Hôpital Sud, Rennes, France,* [2]*Laboratoire de génétique moléculaire - CHU Pontchaillou, Rennes, France,* [3]*UMR 6061 CNRS, IFR 140 GFAS - Université Rennes 1, Rennes, France,* [4]*Service de Génétique, CHU Hôpital Brabois, Nancy, France,* [5]*Laboratoire de Cytogénétique, Centre Hospitalier, Chambéry, France,* [6]*Laboratoire d'anatomopathologie, CHU Pontchaillou, Rennes, France,* [7]*Laboratoire d'anatomopathologie, CHU Morvan, Brest, France,* [8]*Laboratoire d'anatomopathologie, CHU, Rouen, France,* [9]*INSERM EA 4309, IFR PM 23, Université de Rouen, Rouen, France.*

Rhombencephalosynapsis (RS) is an uncommon, but increasingly recognized, cerebellar malformation defined by vermian agenesis with fusion of the hemispheres. The embryologic and genetic mechanisms involved are still unknown, and to date, no animal models are available.

To detect RS candidate genes, we performed Agilent oligonucleotidic arrays throughout 57 RS patients. Four different unbalanced rearrangements were found out: a 16p11.2 deletion, a 14q12-q21.2 deletion, an unbalanced translocation t(2p; 10q) and particular one microdeletion of 2,7 Mb in the 16p13.11 region containing 2 candidate genes for RS : *c16orf45* and *NDE1.* The sequencing of *c16orf45* performed on the whole cohort did not reveal any mutation. Using *in situ* hybridization to localize gene expression on a chick embryo model, we confirmed the neural expression of *NDE1* and *c16orf45*.

From this first microarray scan series of rhombencephalosynapsis, it could be suggested that its genetic causes are likely heterogeneous.

Chromosomal microarrays in the clinical context: a critical appraisal of algorithms for results interpretation

F. Forzano[1], *G. Mandrile*[1], *V. Uliana*[1], *M. Malacarne*[2], *S. Cavani*[2], *D. Coviello*[2], *C. Marciano*[1], *E. Di Maria*[1,3], *F. Faravelli*[1];

[1]*Medical Genetics Unit, Galliera Hospital, Genova, Italy,* [2]*Laboratory of Genetics, Galliera Hospital, Genova, Italy,* [3]*Dept. of Health Sciences, University of Genova, Genova, Italy.*

Chromosomal microarray analysis has become a first tier examination in intellectual disability, either isolated or combined with congenital malformations. The analysis of its results is still complex and often non-univocal though, making its application in the clinical practice challenging. In the attempt to guide the interpretation, a number of algorithms have been proposed and published over years.. In order to evaluate the clinical utility of the application of array-CGH in our clinical practice, and to appreciate the extent of agreement on the evaluation of the CNVs in literature, we retrospectively analysed a cohort of 74 individuals affected by intellectual disability and malformations, phenotypically and genotypically analysed in the years 2005-2010. We compared our own evaluation against 6 algorithms published in the same time frame. We detected 41 CNV in 31 patients, with a CNV detection rate of 42%; 9.5% of patients had more than one CNV. In 47% of cases the CNV had been deemed pathogenic, in 5% benign and in 48% some degree of uncertainty (VOUS) remained. When comparing our evaluation with the different algorithms, and the algorithms themselves to each other, we found that only in a third of cases the assessment was fully concordant, in another third at least one algorithm was discordant, in the last third 2 or 3 algorithms were discordant. Furthermore, we noticed that over the years the CNVs' categorization is more and more cautious with a progressive widening of the VOUS categories and a parallel decrease of the certainties.

P02.020

Characterization of a new Complex Chromosome Rearrangement (CCR) between chromosome 3 and chromosome 8

L. Rodríguez[1], *M. García-Castro*[1], *A. Plasencia*[2], *J. Fernández-Toral*[2], *S. Bhatt*[3], *T. Liehr*[3], *E. Abarca*[1];

[1]*Laboratorio AbaCid-Genética. Grupo Hospital de Madrid, Madrid, Spain,* [2]*Unidad de Genética del Hospital Central de Asturias, Oviedo, Spain,* [3]*Jena University Hospital, Institute of Human Genetics, Jena, Germany.*

Background: Complex Chromosome Rearrangements (CCRs) are defined as structural chromosomal rearrangements with at least three breakpoints and exchange of genetic material between two or more chromosomes. To date, more than 255 cases of CCRs involving three or more chromosomes have been reported, although their incidence seems to be increasing because of the impact of the application of new molecular technologies. Nevertheless, CCRs involving two chromosomes are still very rare.

Objective: To identify the origin and chromosomes involved in a CCRs.

Material and Methods: Here we present a malformed newborn female with a partial trisomy of the long arm of a chromosome 3, which at first was considered to be a derivative of a balanced maternal translocation and, after the application of high resolution cytogenetic techniques, array-CGH analysis, Fluorescence in situ Hybridization (FISH) and Multi Color Banding FISH (MCB), was found to be a CCR derived from a maternal insertion.

Conclusion: With the presentation of this case, we would like to reinforce the power of MCB and array-CGH for clarifying any type of CCRs, as previously proposed by Pellestor et al. [2011] and Kang S-HHL [2010], but also to support the value of a high resolution G-Band karyotype and the idea that "all techniques are complementary and provide different information, essential to understand all kinds of CCR".References: Kang S-HL et al., 2010; Lee et al., 2010; Madan K, 2012; Viaggi et al. 2012; Pellestor et al. 2011 and Kang S-HHL et al., 2010.

P02.021

Defining the minimal critical region for the 3p deletion syndrome.

C. Pinato, *C. Rigon, M. Cassina, L. Salviati, M. Clementi;*

Department of Women's and Children's Health, University of Padova, Italy, Padova, Italy.

The 3p deletion syndrome is a rare disorder characterized by mental and psychomotor retardation, microcephaly, short stature, hypotonia, postaxial polydactyly and dysmorphic craniofacial features, such as ptosis and blepharophimosis. Most of the reported cases have a large terminal 3p deletion, ranging from 6Mb to 12Mb, but the clinical use of microarray-based analysis has recently led to the identification of smaller interstitial deletions on 3p25, from 643Kb to 1.6Mb.

We report the case of a 2 year old male patient with the typical features of the 3p-syndrome: psychomotor retardation, craniofacial dysmorphism, postaxial polydactyly and hypotonia. Array-CGH analysis detected a de novo 371 Kb deletion on 3p25.3, including few genes whose function is still partially unknown. Among the deleted region, MTMR14 (myotubularin related protein 14) appears to be the best candidate gene to explain some of the clinical features, such as hypotonia and some craniofacial dysmorphisms, since it plays a critical role in muscle calcium homeostasis and Mtmr14-null mice showed muscle weakness and increased fatigue compared to wildtype mice. Few cases of 3p25 deletion with features of the 3p-syndrome have been reported so far in the literature. The deletion of 371Kb we observed in our patient overlaps with those previously reported and enables to better define the minimal critical region responsible for 3p-syndrome.

P02.022

Expanding the clinical phenotype at the 3q13.31 locus with a new case of microdeletion and first characterization of the reciprocal duplication.

M. Vuillaume[1,2], *S. Naudion*[1], *M. Delrue*[1,2], *J. Toutain*[1], *P. Fergelot*[1,2], *B. Arveiler*[1,2], *D. Lacombe*[1,2], *C. Rooryck*[1,2];

[1]*CHU Bordeaux, Service de Génétique Médicale, Bordeaux, France,* [2]*Univ. Bordeaux Segalen, Laboratoire Maladies Rares : Génétique et Métabolisme (MRGM), EA 4576, Bordeaux, France.*

Congenital deletions of 3q13.31 region have been recently described as a novel microdeletion syndrome characterized by developmental delay, postnatal overgrowth, hypoplastic male genitalia and characteristic facial features. A common critical region of overlapping of 580 kb was delineated including two strong candidate genes for developmental delay: *DRD3* and *ZBTB20*.

In this report, we describe a new case of 3q13.31 microdeletion identified by array-CGH in a 16 year-old girl sharing clinical features commonly observed in the 3q13.31 microdeletion syndrome. This girl had a microdeletion of 7.39 Mb spanning the common critical region of overlapping.

More interestingly, we report for the first time the existence of a microduplication reciprocal to the microdeletion syndrome. This familial 2.76 Mb microduplication identified by array-CGH was carried by two brothers and their father. The phenotype shared by the brothers was resembling to the phenotype related to the 3q13.31 microdeletion syndrome including especially developmental delay, behavioral abnormalities and obesity. This mi-

croduplication involves three strong candidate genes for the developmental delay *ZBTB20, LSAMP* and *GAP43*. Further molecular characterization showed that *DRD3*, another strong candidate gene for developmental delay, was not included in the duplicated region. A dosage alteration of this gene cannot be completely excluded as the duplication was inverted at proximity of this gene, as shown by *FISH* analysis. Finally, we hypothesized that the phenotype shared by the two brothers could be related to a gene dosage imbalance even if gene expression could not be measured in target tissues such as brain or adipocytes.

P02.023

The 3q13.31 Microdeletion syndrome: A new patient molecularly characterised using array-CGH

D. Trost[1], *A. Bazin*[1], *P. Kleinfinger*[1], *L. Lohmann*[1], *J. Furioli*[2], *G. Viot*[3];
[1]*Laboratoire CERBA, Saint Ouen l'Aumone, France,* [2]*Hôpital de Mantes, Pédiatrie, Mantes la Jolie, France,* [3]*Hôpital Cochin, Paris, France.*

Microdeletions in 3q13.31 have been reported in only relatively few patients to date and only a subset of cases have been characterised at molecular resolution. The deletion size for most patients is larger than 5 Mb, some smaller deletions allowed previously to define a smallest region of overlap (SRO).
Apart from intellectual disability / developmental delay (ID/DD) of varying degrees, which is common to all reported patients, the clinical spectrum comprises speech delay, muscular hypotonia, skull malformations, ocular malformations, skeletal malformations and dysmorphic features.
Here, we report a female patient with a 3.4-Mb *de novo* deletion of 3q13.31. She was born at 38 week of gestation, birth weight 3940g (+1 SD), birth height 51cm (normal), occipiofrontal circumference (OFC) 37cm (+1 SD).
Her clinical presentation at the age of 21 month includes: weight 1100g (-1 SD), height 82cm (normal), OFC 51cm (+2,25 SD), mild DD, severe muscular hypotonia, macrocephaly, strabismus, hypermetropia and dysmorphic signs including hypertelorisme, anti-mongoloid slanted eyes, everted upper lip with a "tented" appearance and retrognathia.
The deleted segment of chromosome 3 (chr3:112.144.025-115.514.432) contains 24 RefSeq genes and comprises the previously defined SRO.Our patient with a relatively small deletion of 3.4-Mb confirms the pertinence of the previously delineated SRO and helps to identify the core phenotype of the 3q13.31 microdeletion syndrome.

15q11 microduplication in a boy with psychomotor delay and PWS-like phenotype

V. Belengeanu[1], *M. Stoian*[2,3], *C. Popescu*[1], *S. Farcas*[3], *N. Andreescu*[3], *A. Belengeanu*[4], *D. Misceo*[5];
[1],,*Vasile Goldis" Western University of Arad, Department of Genetics, Arad, Romania,* [2]*Personal Genetics-Medical Genetics Center, Bucharest, Romania,* [3]*University of Medicine and Pharmacy "Victor Babes" of Timisoara, Department of Morphologic Microscopy, Discipline of Genetics, Timisoara, Romania,* [4]*University of Medicine and Pharmacy "Victor Babes" of Timisoara, Department of Morphologic Microscopy, Discipline of Molecular and Cellular Biology, Timisoara, Romania,* [5]*Olso University Hospital and University of Oslo, Department of Medical Genetics, Oslo, Norway.*

In the literature, the duplications of Prader-Willi/Angelman syndrome critical region 15q11q13 are separate genomic syndrome (OMIM number: 608636). The patients exhibit predominant different neurodevelopmental disorders such as autism, seizures, developmental delay, clumsiness, schizophrenia or schizoaffective patterns. Minor dysmorphic features such as macrocephaly, down-slanting palpebral fissures, broad nasal bridge, pouting lips, expressionless face, frontal tuft of hair were presented in many cases in various combinations.
We report the 9 years old boy for developmental delay, only slight dysmorphic facial features and obesity with a PWS-like phenotype. His height is 140 cm, weight 51 kg (>75thcentile) and OFC 54 cm (>90thcentile). He had facial dysmorphisms reminiscent of PWS with small almond-shaped eyes, small down-turned mouth, small hands and feet, generalized obesity (BMI=26, >97thcentile). He also presented developmental delay (QIP=96, QIG=87), especially of speech (QIV=85) and he followed speech therapies. His mother has similar dysmorphic phenotype: small stature (151 cm), obesity (102 kg) and learning difficulties at school. The family history was significant for obesity (maternal grandfather).Tests for Prader syndrome were FISH using Vysis-Abbott Prader-Willi/Angelman Region LSI SNRPN(SO)/CEP15(SG)/PML(SO), LSI D15S11(SO)/CEP15(SG) and LSI D15S11(SO)/CEP15(SG)/PML(SO). The genetic analyses with normal results included chromosome analyses (550 band level) for PWS.
Array comparative genomic hybridization (aCGH) was carried out on the SurePrint G3 Unrestricted CGH ISCA v2, 4x180K Agilent oligoarray CGH, according to manufacture's instruction and analyzed by CytoGenomics v2.0.6.0 (Agilent Technologies, CA, USA). ArrayCGH detected a 1.5Mb duplication on 15q11 (chr15:22,373,313-23,889,744 GRCh37/hg19). We report and compare our propositus with previously reported patients with 15q11 duplication.

Confirmation of atypical features in auriculocondylar syndrome caused by recessive PLCB4 mutations

Y. Kido[1], *S. Sakazume*[1], *C. T. Gordon*[2], *E. B. Bdira*[2], *S. Lyonnet*[2], *N. Murakami*[1], *M. L. Cunningham*[3], *J. Amiel*[2], *T. Nagai*[1];
[1]*Division of Clinical Genetics, Dokkyo Medical University Koshigaya Hospital, Koshigaya, Japan,* [2]*INSERM U781, Département de Génétique, Hôpital Necker-Enfants Malades and Université Paris Descartes–Sorbonne Paris Cité, Institut Imagine, Paris, France,* [3]*Department of Pediatrics, University of Washington and Seattle Children's Hospital Craniofacial Center, Seattle, WA, United States.*

Auriculocondylar syndrome (ACS; MIM 602483 and 614669) is a branchial arch syndrome typically inherited in an autosomal dominant fashion. Patients with ACS display the following core symptoms with varying severity: a specific malformation of the external ear, known as a 'question mark ear', micrognathia and mandibular condyle hypoplasia. Recently, phospholipase C, β 4 (PLCB4) mutations were identified as the major cause of autosomal dominant ACS, with mutations of the PLCB4 catalytic domain predicted to have a dominant negative effect. In addition, one ACS patient born to related parents harbored a homozygous partial deletion of PLCB4, and presented core features of ACS plus central apnea and macropenis; these features had not been previously reported in association with ACS. This case suggested autosomal recessive inheritance of ACS, with complete loss of function of PLCB4. We herein describe two patients with ACS caused by PLCB4 compound heterozygous splice site mutations. The patients were born to the same unrelated parents, and the parents did not show any features of ACS. Sequencing of PLCB4 revealed the compound heterozygous mutations c.854-1G>A and c.1238+1G>C in both of the patients, with each parent harboring one of the mutations, indicating autosomal recessive ACS. Both of the patients reported here had central apneas, gastrointestinal transit defects and macroenis, in addition to typical craniofacial features of ACS. This is the first example of patients with ACS caused by compound heterozygous splice site mutations in PLCB4, and the second autosomal recessive cases of ACS confirmed by the molecular analysis.

Map of Autosomal Recessive Genetic Diseases in Saudi Arabia: Concepts and Future Directions

M. A. Al-Owain[1,2];
[1]*King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia,* [2]*Alfaisal University, Riyadh, Saudi Arabia.*

Saudi Arabia has a population of 27.1 million and an overall consanguinity rate of 56%. Prevalence of many autosomal recessive disorders is higher than other known populations. This is attributable to the high rate of consanguineous marriages, the tribal structure, and the large family size. Founder mutations have been recognized in many autosomal recessive disorders, many of which are overrepresented within certain tribes. On the other hand, allelic heterogeneity is also observed among common and rare autosomal recessive conditions. **With the adoption of more advanced molecular techniques in the country in recent years in conjunction with international collaboration, t**he mapping of various autosomal recessive disorders has dramatically increased. Different genetic concepts pertinent to this highly inbred population are discussed here. Addressing such genetic diseases at the national level will become a cornerstone of strategic health care initiatives in the 21st century. Current efforts are hampered by many socio-cultural and health care related factors. Education about genetic diseases, establishment of a "national registry" and mutational database, and enhanced healthcare access are crucial for success of any preventative campaign.

Baraitser-Winter syndrome: genotype-phenotype correlation and clinical variability of the recurrent *ACTB* mutation

N. Di Donato[1], *A. Rump*[1], *V. M. Der Kaloustian*[2], *F. Halal*[2], *K. Sonntag*[1], *K. Hackmann*[1], *G. Hahn*[3], *E. Schrock*[1], *J. Masliah-Planchon*[4], *A. Verloes*[4];
[1]*Institut für Klinische Genetik, Dresden, Germany,* [2]*Department of Medical Genetics, Montreal Children's Hospital, Montreal, QC, Canada,* [3]*Institut und Poliklinik für Radiologische Diagnostik, Universitätsklinikum, Dresden, Germany,* [4]*Department of Genetics, Robert-Debré hospital, Paris, France.*

ACTB and ACTG1 mutations have recently been reported to cause Baraitser-Winter syndrome (BRWS) - a rare condition characterized by ptosis, colobomata, neuronal migration disorder, distinct facial anomalies, and intellectual disability (Riviere et al. PMID:22366783). ACTB and ACTG1 code for the beta- and
gamma isoforms of actin - two nearly identical highly conserved proteins that differ only by four amino acids.
The ACTB mutations c.586C>T and c.587G>A, both affecting the Arg196 codon, are recurrent. One of the patients carrying the ACTB
mutation c.587G>A (p.Arg196His) was previously diagnosed with Fryns-Aftimos syndrome (FAS). Expanding our cohort of BRWS patients we observed the c.586C>T(p.Arg196Cys) mutation in four patients with classical BRWS and in one of the severely affected patients assigned as having FAS, who shows malformations beyond the BRWS spectrum, like double halluces (Der Kaloustian et al. PMID:11311002). Furthermore, we identified a novel ACTB mutation c.359C>T (p.Thr120Ile) in a patient strikingly resembling an individual reported by Der Kaloustian et al. This patient exhibits double halluces.
The ACTB mutation c.359C>T (p.Thr120Ile) is analogous to the ACTG1 mutation NM_001614.1:c.359C>T previously reported in a patient with classical BRWS (significantly milder affected than patient analyzed here).Taking together, BRWS and FAS represent the severity range of the same clinical entity. Despite the structural similarity of beta- and gamma-actins and their overlapping expression pattern, mutations in ACTB cause a distinctly more severe phenotype than ACTG1 mutations. The recurrent ACTB mutation c.586C>T (p.Arg196Cys) may result in classical BRWS phenotype as well as in severe BRWS formerly known as FAS.

Bardet Biedel Syndrome in South Africa: The Clinical Phenotype of a Single Mutation in BBS 10.

K. J. Fieggen[1], *C. Milligan*[1], *A. Esterhuizen*[1], *B. Henderson*[2], *A. Wonkam*[1], *E. Heon*[3];
[1]*University of Cape Town, Cape Town, South Africa,* [2]*University of Free State, Bloemfontein, South Africa,* [3]*University of Toronto, Toronto, ON, Canada.*

Background: Bardet Biedel syndrome (BBS) is a pleiotropic disorder characterized by obesity, polydactyly, intellectual disability and a progressive retinopathy. It is a highly heterogenous autosomal recessive disease. Homozygosity for single mutation in BBS 10 has been identified in a number of affected individuals tested in South Africa.
Objectives: To delineate the ethnic distribution and clinical phenotype in a cohort of South African BBS patients with the K2431fsX15 mutation in BBS 10 and review the implications for genetic testing and counseling in this disorder in South Africa.
Method: A descriptive cross sectional study collating clinical data retrospectively in a genetically homogenous group of BBS patients from South Africa.
Results: A total of 38 patients from 37 families were tested. 27 of these (71%) were homozygous for the K2431fsX15 BBS 10 mutation. BBS is more common in Black South Africans from different language groups (32 of 37 families). Of those homozygous for this mutation, 26 (96%) shared this ethnicity. The phenotype showed characteristic variability. The onset of visual disability was early in our cohort and renal abnormalities were infrequently encountered.
Conclusions: The high frequency of homozygosity for a single mutation in an ethnic subset of the South African population is suggestive of a founder effect. This has allowed establishment of a cost effective diagnostic test for a single mutation with a high yield in our local population. Appreciation of the phenotype may improve earlier recognition of the disorder to allow for appropriate intervention.

P02.029

Trisomy 11p15.5 and monosomy 13q34 in a girl with Beckwith-Wiedemann syndrome and Factor VII deficiency.

D. Jurkiewicz[1], *M. Kugaudo*[1,2], *A. Tańska*[1], *A. Wawrzkiewicz-Witkowska*[3], *A. Tomaszewska*[3], *M. Kucharczyk*[1], *E. Ciara*[1], *K. Chrzanowska*[1], *M. Krajewska-Walasek*[1];
[1]*Department of Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland,* [2]*Department of Child and Adolescent Psychiatry, Medical University of Warsaw, Warsaw, Poland,* [3]*Prenatal Diagnostic and Genetic Clinic, Medical University of Silesia, First Hospital, Zabrze, Poland.*

Here we report an one-year-old patient recruited to genetic analysis because of developmental delay and the presence of specific for Beckwith-Wiedemann syndrome (BWS) phenotype (five major and four minor clinical criteria of BWS was stated). Moreover, she had reduced level of Factor VII. Initial conventional karyotyping was normal. MS-MLPA (methylation specific multiplex ligation-dependent probe amplification) revealed increased hybridization signals as well as aberrant methylation of specific probes in 11p15.5. The duplication was than confirmed by aCGH indicating 4.68 Mb distal duplication in 11p15.5; besides 2.96 Mb distal deletion within 13q34 was identified. Most of the patient's clinical findings are typical of BWS, whereas developmental delay and distinctive craniofacial phenotype (prominent occiput, flat forehead with frontal bossing, round face with full cheeks, hypertelorism, flat nasal bridge and short palpebral fissures) are the features typical of trisomy 11p15. Reduced level of Factor VII might be explained by deletion of 13q34 in combination with a mutation in the factor gene located in that region on the other chromosome 13, considering that Factor VII deficiency is a recessive disorder. To our knowledge this is a first report of 11p15.5 duplication associated with deletion of 13q34 and Factor VII deficiency. The study underlines the importance of detailed clinical description and indicates that aCGH should be performed in all BWS patients with copy-number abnormalities detected by MS-MLPA and normal conventional karyotype to avoid overlooking of a cryptic unbalanced translocation.
The study was financed by National Science Centre, project 1149/B/P01/2011/40 (NN407114940) and EU Structural Funds, project POIG.02.01.00-14-059/09.

Different methylation patterns in Beckwith-Wiedemann syndrome due to mosaicism for UPD of chromosome11p15

E. Ciara[1], *D. Jurkiewicz*[1], *M. Kugaudo*[1,2], *A. Tańska*[1], *M. Ginalska-Malinowska*[1], *D. Piekutowska-Abramczuk*[1], *M. Pelc*[1], *S. Łuczak*[1], *J. Trubicka*[1], *P. Kowalski*[1], *M. Borucka-Mankiewicz*[1], *A. Jezela-Stanek*[1], *K. Chrzanowska*[1], *M. Krajewska-Walasek*[1];
[1]*The Children's Memorial Health Institute, Warsaw, Poland,* [2]*The Medical University of Warsaw, Warsaw, Poland.*

Molecular abnormalities in the 11p15.5 imprinted gene cluster lead to Beckwith-Wiedemann syndrome (BWS), characterized by overgrowth, macroglossia, abdominal wall defects and embryonal tumors. The most common defect in BWS is loss of methylation at imprinting 11p15 control region (~50% of cases). Approximately 20% of individuals fulfilling diagnostic criteria for BWS have paternal UPD for 11p15 critical region. We report eight cases with BWS due to patUPD of 11p15 with the aim to evaluate the percentage of mosaicism. The diagnosis in our patients was established by methylation sensitive multiplex ligation-dependent probe amplification (MS-MLPA) on leukocyte DNA. Microsatellite analysis of chromosome region 11p15, performed in 6 families, confirmed mosaicism for segmental isodisomy at the short arm of chromosome 11. Different methylation pattern in both, H19DMR and KvDMR, domains was observed for each patient, but there has been no correlation between the percentage of mosaicism and methylation index. Clinical presentation of our patients includes variable manifestation of BWS. Only macroglossia and hemihyperplasia were constant symptoms in almost all cases. Clinical heterogeneity is likely due to the variable levels of mosaicism in different tissues. Testing of other tissues than blood in BWS individuals with complex clinical presentations could be a valuable diagnostic tool to improve the detection rate of mosaic paternal UPD. Identification of individuals with mosaicism for paternal UPD is an important goal as identifies individuals who require surveillance due to increased tumor risk.
Study was financed by National Science Centre, project 1149/B/P01/2011/40 (NN407114940) and EU Structural Funds, project POIG.02.01.00-14-059/09.

Beckwith-Wiedeman syndrome - diagnostic experiences in Slovakia

D. Durovcikova[1], *D. Durovcikova*[1], *A. Krepelova*[2], *I. Mlkva*[3], *K. Vicianova*[4], *M. Pechová*[1];
[1]Slovak Medical University, Bratislava, Slovakia, [2]Charles University, 2nd Faculty of Medicine, Dept of Biology and Med.Genet, Praque, Czech Republic, [3]University Hospital, Bratislava, Slovakia, [4]Children´s University Hospital, Bratislava, Slovakia, Bratislava, Slovakia.

Beckwith-Wiedeman syndrome (BWS) is a rare genetic disease associated with owergrowth and predisposition to tumor development in childhood. The incidence of BWS in different ethnic group is estimated to be 1 out of 13 700 (Weksberg, 2010).
We present prevalence data in Slovakia, some of clinical data, diagnostic approaches and testing strategy for patient with BWS phenotype. Basic information about BWS prevalence in Slovakia was obtain from Genetic register and by personal communication with Slovak clinical geneticist.
The diagnosis of BWS was reported in 17 cases in 2006, determined solely on the basis of clinical signs EMG syndrome. The total capture of BWS in 2011 includes 25 cases. Early BWS clinical diagnosis within 1 year of life and varying severity of clinical symptoms, different molecular pathology in 3 female cases is documented. Loss of methylation at KVDMR1 was confirmed in mild BWS phenotype with occurence of neuroblastoma. Mutation CDKN1C - c.517dupG (p.Va1173GlyfsX68) was detected in newborn patient with serious omphalocele and renal dysplasia.Generally, in patient with BWS phenotype, except of chromosomal analysis, determination of altered methylation, microdeletion at imprinting center 1(IC1)and/ or (IC2) or mutation in CDKN1 by DNA tests helped confirm BWS diagnosis definitelly. Recent scientific findings and clinical experiences together with activities Eu in the field of the rare diseases pointed to an expanding range of medically indication for genetic testing, which may have important role for health care management, including BWS patients

Blepharophimosis, ptosis, epicanthosis inversus syndrome (BPES) with FOX L2 mutation and congenital hydronephrosis - a new association.

R. Gulati[1], *D. Halanaik*[2], *V. Bhat*[1], *E. De Baere*[3];
[1]Department of Pediatrics, Jawaharlal Institute of Postgraduate Medical Education and Research, Pondicherry, India, [2]Department of Nuclear Medicine, Jawaharlal Institute of Postgraduate Medical Education and Research, Pondicherry, India, [3]Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Blepharophimosis, ptosis, epicanthosis inversus syndrome (BPES) (OMIM 110100) is an autosomal recessively inherited congenital malformation of eyelids which can potentially lead to loss of vision. Squint, refractory errors and amblyopia can develop as complications. Diagnosis is based on clinical findings of bilateral blepharophimosis, ptosis, epicanthus inversus and telecanthus. Type includes these four major criteria. Type includes additional feature of premature ovarian failure and female infertility. We report for the first time a 1 year old male child with congenital hydronephrosis associated with typical features of BPES. He was the first-born to non-consanguineous parents. His father had similar but less severe features. Growth and development were appropriate for age. Echocardiogram was normal. Congenital bilateral hydronephrosis and reduced kidney function were confirmed by renal dynamic scan. Sequencing was performed on FOX L2, the only gene associated with BPES. The normal gene has 14 Alanine repeats. Sequencing of the only intron of FOX L2 revealed the patient to be heterozygous for mutation p.Ala225_Ala234dup (c.672_701dup) which is a recurrent 30 bp duplication, an expansion of the poly-Ala tract. It represents 30% of mutations found in BPES patients and is usually associated with Type. Some additional atypical findings like growth hormone deficiency, ventricular septal defect, Burkitt's lymphoma and Duane syndrome, associated with this mutation have been reported previously. The atypical finding of hydronephrosis may have resulted from a pleiotropic effect of the mutation. It is not possible to know the type of BPES in our patient as no female family member is affected.

Congenital malformations affect approximately 2.5% of stillborns. Among these defects, brain abnormalities are the main malformations detected prenatally. Mostly (60%) are sporadic without explanation. Improvements of ultrasound prenatal screening combined to 3rd trimester fetal Magnetic Resonance Imaging (MRI) increase detection cerebral malformations. In most cases termination of pregnancy was elected. Foetopathological examination identified other associated malformations in approximately 50% of the cases. No explanation can be offered for about 50% of cases.
An increasing number of congenital malformations have been identified as a result of a genomic disorder using new techniques analysis of a whole genome. We study a cohort of 100 fetuses with a syndromic cerebral malformation divided into 4 groups (neural tube defects, cerebellum hypoplasia, commissural abnormalities, or microcephaly) by aCGH. The aim of this study was to identify potential new genes involved in brain development.
The cases were included with the participation of fetal pathologists, cytogenetics laboratories and biobanks and thanks to the collaboration of the French Society of fetal pathology (SOFFOET). Fetal DNA was extracted, and aCGH was performed on 180K chips (Agilent). We identified 11 de novo pathogenic CNVs and 3 inherited pathogenic CNVs. Several CNVs included a gene already known to be involved in the brain development such as NDE1 or NFIA. In particular we described the first female fetus with cerebellar hypoplasia and partial de novo OPHN1 deletion. We also identified several CNVs highlighting new interesting loci. Here, we present our results and discuss the new CNVs identified.

Associated malformations among patients with CAKUT (congenital anomalies of kidney and urinary tract)

C. Stoll, *B. Dott, Y. Alembik, M. Roth;*
Genetique Medicale, Strasbourg, France.

Infants with congenital anomalies of kidney and urinary tract (CAKUT) often have other associated malformations. The purpose of this investigation was to assess the prevalence and the types of associated malformations in CAKUT in a defined population. Each affected child was examined by a geneticist, all elective terminations were ascertained, and the surveillance for malformations was continued until 2 years of age. The associated malformations in
CAKUT were collected in all livebirths, stillbirths and terminations of pregnancy during 26 years in 347,810 consecutive births in the area covered by our population based registry of congenital malformations. Of the 1252

infants with CAKUT born during this period (prevalence at birth of 36.0 per 10,000), 410 (32.7 %) had associated malformations. There were 142 (34.6%) patients with chromosomal abnormalities including 15 trisomies 18, and 72 (17.6%) nonchromosomal recognized dysmorphic conditions. There were no predominant recognised dysmorphic conditions, but VA(C)TER(L) association. However, other recognised dysmorphic conditions were registered including Meckel syndrome, osteochondrodysplasia, and caudal regression syndrome. Hundred ninety six (47.8 %) of the patients had multiple congenital anomalies, non syndromic, non chromosomal (MCA). Malformations in the ear, the digestive, the central nervous, and the cardiovascular systems were the most common other malformations. Prenatal diagnosis was performed in 57.8 % of dysmorphic syndromes with CAKUT. The overall prevalence of associated malformations, which was one in three infants, emphasizes the need for a thorough investigation of infants with CAKUT. A routine screening for other malformations may be considered in infants and in fetuses with CAKUT.

P02.035

Congenital heart defect in a patient with a complex rearrangement and a 13q deletion: delineating a new critical region.

L. Mouthon, *M. Dayem-Quere, F. Giuliano, V. Paquis-Flucklinger, H. Karmous-Benailly; Hôpital de l'Archet II, CHU de Nice, Nice, France.*

13q deletion syndrome is a rare genetic disorder caused by deletions of the long arm of chromosome 13. Based on the size and location of the deletion, this syndrome can be divided into three groups, group 3 corresponds to the distal deletion of band 13q33-34. Patients with 13q deletion display a variety of phenotypic features, including growth retardation, microcephaly, facial dysmorphisms, congenital heart, brain and kidney defects. We report the case of a dysmorphic 7-year old male patient displaying polymalformative features and carrying a deletion of approximately 8.57 Mb on 13q33.1q34 (group3), including 20 genes. The phenotype of our patient includes intrauterine growth retardation, developmental retardation, hypospadias, microcephaly, facial anomalies and a congenital heart defect. The deletion size of our patient was further delineated by array-CGH, and precisely located on chromosome 13: 103.941.149-112.512.705 (hg19). Futhermore, we can reduce the critical region to 3 Mb instead of 6 Mb (Huang, 2012). This new chromosomal region contains only 12 genes including *MYO16*, *COL4A1*; *COL4A2*, *ING1* and *ARHGEF7*.
On a cytogenetic point of view, the chromosome 13 of our patient appeared to be a derivative chromosome 13 coming from a complex maternal chromosomal rearrangement involving three chromosomes and four breakpoints. The maternal formula is : 46,XX,t(7;8)(q36;p21),ins(8;13)(p21;q33.1q34). We will discuss the involvement of the deleted genes in the phenotype of our patient and we will also describe the precise mechanisms leading to this rearrangement.

A heterozygous frame-shift mutation in CAV1 is associated with a severe congenital lipodystrophy syndrome

I. Schrauwen[1,2], *S. Szelinger*[1], *A. L. Siniard*[1], *A. Kurdoglu*[1], *J. J. Corneveaux*[1], *I. Malenica*[1], *D. W. Craig*[1], *V. Narayanan*[1], *M. J. Huentelman*[1];
[1]*Center for Rare Childhood Disorders and the Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ, United States,* [2]*Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.*

We investigated a single female patient and unaffected parents presenting with a neonatal progeroid disorder, lipodystrophy, cutis marmorata, feeding disorder and failure to thrive by whole-genome sequencing. This revealed a de novo, heterozygous, frame-shift mutation in the Caveolin1 gene (CAV1), which introduces an immediate stop into the protein (c.385_386delTT; p.Phe129X). Mutations in CAV1, encoding the main component of the caveolae in plasma membranes, cause Berardinelli-Seip congenital lipodystrophy type 3. Although this disorder is recessive, heterozygous carriers either show a reduced phenotype of partial lipodystrophy or no phenotype. We could not identify a second mutation in CAV1 in our patient. Studying mRNA extracted from whole blood from the patient revealed that both MT and WT CAV1 were transcribed, and that RNA from the mutant allele was not degraded by nonsense mediated RNA decay. We therefore hypothesize that the mutant protein is expressed in our patient and acts in a dominant negative fashion, leading to a severe lipodystrophy phenotype. Introduction of this mutant CAV1 could disturb the stable and functional hetero-oligomeric complex formed by Cav1 and Cav2, or disturb cellular localization. We will therefore introduce MT and WT CAV1 in a stable cell line to study the effect of the mutant protein on wild type function and localization.
In conclusion, we suggest that the severe phenotype observed in our patient might be caused by a dominant-negative effect of MT CAV1, and that the presence of a partial lipodystrophy phenotype found in some patients might be dependent on the type of CAV1 mutation.

Searching for the disease gene in a cerebellar ataxia family

Ö. Ayhan[1], *B. Kara*[2], *G. Gökçay*[3], *N. Başboğaoğlu*[4], *A. Tolun*[1];
[1]*Boğaziçi University, Istanbul, Turkey,* [2]*Kocaeli University, Kocaeli, Turkey,* [3]*Istanbul University, Istanbul, Turkey,* [4]*Düzce University, Düzce, Turkey.*

Autosomal recessive ataxia is characterized by progressive lack of coordination of muscle movements. We studied two brothers at the age of 38 and 40 years with initial diagnosis of cerebellar ataxia. The parents were second cousins. The patients walked and spoke single words by the age of 2 years, and progressive ataxic gait and visual impairment began in early childhood. At present the patients have ataxic gait, dysmetria, dysdiadochokinesia, scanning speech and intellectual disability. Additionally, eye examination showed bilateral horizontal nystagmus, posterior subcapsular cataract, optic disk hypoplasia, optic atrophy, thinning of the retinal arterioles, and retinal bone spicule pigmentation.
Genotyping data generated by SNP genome scan for the parents and the affected sibs were used to calculate multipoint LOD scores. Four loci yielded the highest score of 2.66. The largest locus was maximally 52 Mb at chromosome 4q12-24. The others were at 6q25.1-25.2, 12p13.31-p13.1, and 22q12.1 and 0.55 to 5.5 Mb in size. We consider the largest locus (4q12-24) the most likely disease locus but will search for the genetic defect underlying the disease in all four candidate loci. No similar diseases were mapped to any of the loci. The four candidate loci harbor a total of 638 genes. The abundance of the genes discouraged us from applying candidate gene approach, and we launched exome sequencing. Exome sequencing data will be evaluated for those regions, and Sanger sequencing will be performed to validate candidate mutations.

Cerebro-facio-thoracic dysplasia (CFTD; MIM 213980) is a multiple congenital anomaly and intellectual disability syndrome involving the cranium, face and thorax. The characteristic features are cranial involvement with macrocrania at birth, brachycephaly, various CT/MRI findings frequently involving corpus callosum and septum pellucidum, flat face, hypertelorism, epicanthal folds, synophrys, broad nasal bridge, cleft lip and cleft palate, low-set, posteriorly rotated ears, short neck, and multiple costal and vertebral anomalies. The underlying genetic defect remains unknown. Using a combination of homozygosity mapping and whole-exome sequencing, we identified a homozygous nonsense founder mutation, p.R87X (c.259 C>T), in the human transmembrane and coiled-coil domains protein 1 (*TMCO1*) in four out of five families with Turkish origin. RNA studies on lymphocytes indicated that the mutated TMCO1 transcript is degraded by nonsense-mediated mRNA decay. *TMCO1* gene on chromosome 1q24 was excluded by homozygosity mapping and DNA sequencing analysis in the fifth family with characteristic findings of CFTD. These data provided the first evidence for genetic heterogeneity in this spectrum. Another founder *TMCO1* mutation has recently been reported to cause a unique genetic condition, TMCO1-defect syndrome (MIM 614132), characterized by craniofacial dysmorphism, skeletal anomalies and intellectual disability in 11 individuals in the Old Order Amish of

northeastern Ohio. Phenotype comparison between Turkish and American families clearly demonstrated that TMCO1-defect syndrome meets diagnostic criteria for CFTD which was first described by Pascual-Castroviejo et al. in 1975. Our study demonstrated that TMCO1-defect syndrome, initially believed to represent a distinct disorder, indeed belongs to the genetically heterogeneous cerebro-facio-thoracic dysplasia spectrum.

CHARGE syndrome (CS) is a rare usually sporadic disorder with multiple congenital anomalies mainly due to de novo truncating mutations of CHD7 gene.

Here we report a series of 20 CS patients carrying a nucleotide variation located in CHD7 IVS25 (c.5405-7G>A, c.5405-13G>A, c.5405-17G>A or c.5405-18C>A). Among these 4 different variants, two of them (-13G>A and -18C>A) were first isolated in our laboratory, the others were previously classified as variants with unknown clinical significance (-7G>A) and pathogenic (-17G>A). In each case, bioinformatics tools clearly indicated an activation of a newly created acceptor splice site. Splicing defect was then evaluated by minigene assays using an exon-trap derived construct: pSpliceExpress (Kishore et al., 2008). Our study demonstrates that alternative acceptor splice sites generated by the four IVS25 variants were exclusively used by splicing machinery giving rise to a longer exon 26. With the exception of the -17G>A which preserves the normal ORF, the three others correspond to frameshift mutations. Although all patients fulfilled diagnostic criteria of CS we observed phenotypic variability, especially within 2 cases where the mutation (c.5405-17G>A) was inherited from a mildly affected parent. Recurrence of these variations could be explained by a particular genomic context: i) the weakness of the exon 26 natural acceptor site, ii) the lack of a real lariat sequence detected within hundred nucleotides upstream exon/intron boundary.

These data prove the pathogenicity of all the studied variants and indicate the presence of a mutation hotspot in CHD7 IVS25 which is involved in 7% of CS french patients.

CHARGE syndrome (***c***oloboma, ***h***eart defects, ***a***tresia of the choanae, ***r***etarded growth and development, ***g***enital hypoplasia and ***e***ar anomalies) is an autosomal dominant malformation syndrome due to mutations in the chromodomain helicase DNA-binding member *CHD7*. A well established mouse model for this disease is the *Whirligig* mouse (Chd7$^{Whi/+}$), carrying a heterozygous nonsense mutation in exon 11 of the *Chd7* gene. To get molecular insights on the pathogenesis of CHARGE syndrome, we performed a genome-wide microarray expression analysis on wildtype, Chd7$^{Whi/+}$ and Chd7$^{Whi/Whi}$ mouse embryos at day 9.5.We identified 98 genes showing greater than 2 fold differences in expression (log2 fold-change) and a P-value to false discovery rate (FDR) < 0.05 between wildtype and Chd7$^{Whi/Whi}$ embryos. The validation of the microarray data was performed by quantitative real time PCR (qRT-PCR). Interestingly, most genes are involved in neural crest cell induction, formation and migration.

In summary, we could show that misregulation of genes involved in neural crest cell processes is a mechanism behind CHARGE syndrome, demonstrating that CHARGE syndrome belongs to the neurocrestopathies.

Identification of the variations in *CPT1B* and *CHKB* genes in Turkish narcolepsy patients

S. Agılkaya[1], *S. Kaya*[1], *I. Oztura*[2], *D. Karadeniz*[3], *A. Evlice*[2], *B. Baklan*[2], *S. Cingoz*[1];

[1]*Department of Medical Biology and Genetic, Faculty of Medicine, Dokuz Eylul University, Izmir, Turkey,* [2]*Department of Neurology, Sleep Disorders Unit, Faculty of Medicine, Dokuz Eylül University, Izmir, Turkey,* [3]*Sleep Disorders Unit, Cerrahpasa Medical School, University of Istanbul, Istanbul, Izmir, Turkey.*

The rs55770917 variation between *CPT1B* and *CHKB* genes in Japanese and Koreans are common genetic susceptibility factors to narcolepsy. In this study, variations in *CHKB* and *CPT1B* susceptibility genes were examined in Turkish narcolepsy patients.

The *CPT1B* and *CHKB* genes were sequenced in narcolepsy patients (n= 37), and, when available, their parents. Controls (n= 100) were tested for detected variations. rs5770911, rs2269381 and rs2269382 were detected together in three patients and 11 controls, rs55770917 being susceptibility SNP. In addition to this haplotype, we detected the indel variation (rs144647670) in the 5' upstream region of the human *CHKB* gene in the narcoleptic patients and control subjects carrying four variants together. There was no significant difference between patients and control subjects regarding the presence of variant haplotype and allele frequencies of (p =0.62). There was no significant association between rs5770917 and narcolepsy in Turkish patients. However, in our study we found novel haplotype consisting of the indel variation, which had not been detected in previous studies on Japanese and Korean populations, as well as observing four SNPs in *CHKB/CPT1B* .

ALG3-CDG (CDG-Id) presenting with chondrodysplasia punctata: a case report.

L. Lepais[1], *D. Cheillan*[2,3], *S. Collardeau-Frachon*[4,5], *S. Hays*[6], *G. Matthijs*[7], *C. Abel*[1], *P. Edery*[1,5,8], ***M. Rossi***[1];

[1]*Service de Génétique, Groupement Hospitalier Est, Hospices Civils de Lyon, Bron, France,* [2]*Service Maladies héréditaires du métabolisme et dépistage néonatal, Groupement Hospitalier Est, Hospices Civils de Lyon, Bron, France,* [3]*INSERM U.1060/Université Lyon-1, Lyon, France,* [4]*Département de pathologie, Groupement Hospitalier Est, Hospices Civils de Lyon, Bron, France,* [5]*Université Lyon 1, Lyon, France,* [6]*Service de Réanimation néonatale et néonatologie, Hôpital Croix Rousse, Hospices Civils de Lyon, Lyon, France,* [7]*Center for Human Genetics, UZ Gasthuisberg, Leuven, Belgium,* [8]*INSERM, U1028; CNRS, UMR5292; TIGER Team, Lyon, France.*

Chondrodysplasia punctata (CDP) is defined by the radiographic appearance of abnormal cartilaginous stippling. It is generally associated with short stature, maxillofacial hypoplasia and the possible occurrence of multiple

congenital abnormalities (MCA). CDP has been reported in various congenital disorders such as chromosomal abnormalities, disruptions of vitamin K metabolism, and inborn errors of metabolism including peroxisomal disorders, defects of cholesterol biosynthesis and lysosomal storage diseases.
We report two siblings presenting with skeletal dysplasia, CDP and MCA. Patient 1 presented with severe skeletal abnormalities, stippling, vermis hypoplasia, partial corpus callosum agenesis and hepatic fibrosis; the pregnancy was terminated. His sister (Patient 2), showing a similar phenotype (skeletal dysplasia, dysmorphic features, cataract, cerebellar and corpus callosum abnormalities, liver enlargement), died in the neonatal period.
A large metabolic assessment was performed in Patient 2. Screening for congenital disorders of glycosylation (CDG) by Western blot was consistent with "type I" CDG. Phosphomannomutase and phosphomannose isomerase enzymatic assays, performed on patient's fibroblasts, were normal as well as *PMM2* molecular analysis. The analysis of the dolichol linked oligosaccharide precursors was consistent with ALG3-CDG (CDG-Id) and molecular analysis of the *ALG3* gene found a homozygous mutation (p.G96R; c.286G>A), thus confirming the diagnosis.
CDG are a group of metabolic disorders presenting with very heterogeneous multisystem clinical manifestations. To the best of our knowledge, only seven other patients with ALG3-CDG have been described to date. This is the first report of a CDG syndrome presenting with CDP. Screening for CDG should be systematically performed in patients presenting with unexplained CDP.

P02.043
Phenotypic spectrum and diagnostic considerations in children with somatic chromosomal mosaicism

***E. R. A. Thomas**, C. Deshpande, F. Connell, C. Ogilvie, D. Josifova;*
Guy's Hospital, London, United Kingdom.

Chromosomal mosaicism typically presents with developmental delay, dysmorphic features, asymmetry and characteristic variation in skin pigmentation following Blaschko's lines. Seizures and other congenital anomalies may also be present. Array-CGH in blood detects mosaicism down to a level of around 10%, but the abnormal cell line may not be present in blood cell lineages. In these circumstances the diagnosis can be confirmed by carrying out array-CGH on cultured skin fibroblasts. We present several cases which exhibit the wide phenotypic spectrum of chromosomal mosaicism. This includes presentation with typical features such as pigmentary abnormalities or hemihypertrophy, but also an unusual presentation with complex congenital malformations and developmental delay with none of the canonical features. Array-CGH in blood was normal in the majority of cases regardless of age at testing, and the investigative route to diagnosis was therefore variable and complex. The abnormal cell lines included mosaicism for diploid/triploidy, trisomy and large chromosomal imbalance. There was little or no phenotypic correlation with the precise chromosomal abnormality. We also discuss the differential diagnoses including Hypomelanosis of Ito, Incontinentia pigmenti and Nevus depigmentosus. The low sibling recurrence risk attached to the diagnosis of mosaicism makes confirmation important for affected families. Atypical clinical features may lead to a diagnostic odyssey before confirmation, frequently as a result of skin biopsy. This series of cases suggests that skin biopsy should be considered at an earlier stage in a wider spectrum of clinical presentations than is usual in current practice.

P02.044
Orofacial clefts associated with other congenital abnormalities seen at a South African multidisciplinary clinic

***E. M. Honey**[1], H. J. S. van den Berg[2], S. M. du Plessis[3], K. Butow[3];*
[1]Department Genetics, University of Pretoria, Pretoria, South Africa, [2]Department of Maxillo-facial and Oral Surgery, University of Pretoria, Pretoria, South Africa, [3]Department of Maxillo-Facial and Oral Surgery, University of Pretoria, Pretoria, South Africa.

Clefts involving the lip and/or palate (CLP) or isolated clefts of the palate (CP) are among the most common congenital anomalies and require complex multi-professional treatment. The incidence varies according to geographical region, ethnicity and socio-economic status with a general accepted incidence in the Caucasian population of 1:800 to 1:1000. The incidence in the black South African population is unsure but estimated to be lower. Approximately 70% of CLP cases are non-syndromic, occurring as an isolated condition while the remaining 30% are present in association with abnormalities occurring outside the region of the cleft. Over 300 syndromes are known to be associated with CLP.
A retrospective analysis was done of the records of all patients who were registered at the Facial Cleft Deformity Clinic (FCDC) of the University of Pretoria since its founding in 1983.
Of the 3971 patients seen up to date 21% had associated abnormalities. These abnormalities were subdivided according to known described syndromes as part of a Mendelian disorder, demonstrated chromosomal defects; facial oblique clefts; skull synostosis and other unspecified congenital abnormalities.
Advances in the understanding of the aetiology of CLP continue and will prompt more accurate methods of genetic screening, molecular diagnosis and identification of at risk individuals, genetic counselling and prenatal diagnosis.

Drawbacks of genotype-phenotype correlation in Cleidocranial Dysplasia in eleven families

***F. Dincsoy**[1], N. Dinckan[1], Y. Guven[2], U. Altunoglu[1], S. S. Kuvvetli[3], F. Bas[4], O. Z. Uyguner[1], H. Kayserili[1];*
[1]Department of Medical Genetics, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey, [2]Department of Pedodontics, Faculty of Dentistry, Istanbul University, Istanbul, Turkey, Istanbul, Turkey, [3]Department of Pedodontics, Faculty of Dentistry, Yeditepe University, Istanbul, Turkey, Istanbul, Turkey, [4]Division of Endocrinology, Department of Pediatrics, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey.

Cleidocranial dysplasia (CCD) is a dominantly inherited autosomal disorder characterized by abnormally large, wide-open fontanels, delayed closure of the cranial sutures, mid-face hypoplasia, abnormal dentition, clavicular hypoplasia/aplasia and other skeletal abnormalities. Diagnosis could easily be determined by clinical and radiological findings. Affected individuals are shorter than their unaffected sibs. It is reported to be a rare disorder with a frequency of one in a million individuals but the incidence could be higher, since relatively mild or absent medical comlications may go underdiagnosed. Presently, *RUNX2*, encoding an essential transcription factor for osteoblast differentiation, is the only gene associated with CCD. Mutation detection rate is reported to be 60%-70% in affected individuals describing total of 177 mutations in the coding and important splice sites regions of *RUNX2*. The phenotypic spectrum of CCD ranges from a single clinical finding of a primary dental anomalies to a full-blown CCD phenotype, no clear phenotype-genotype correlation has yet been established. One recent article , suggested an association between dental alterations and mutations on runt domain of *RUNX2* gene.
We will report clinical/radiological and molecular findings of 15 affected cases from 11 families. Novel mutations identified in *RUNX2* gene will be discussed in view of the already reported mutations.
We anticipate that our findings will help to gain more perspective for the investigations on genotype/phenotype corelation studies on CCD and its drawbacks.

P02.046
A de novo 6q25.3 deletion comprising *ARID1B* responsible for Coffin-Siris syndrome

***M. Holder-Espinasse**[1], C. Olgivie[2], S. Mathur[3], D. Anderson[3], C. Deshpande[1];*
[1]Clinical Genetics, Guy's Hospital, London, United Kingdom, [2]Cytogenetics, Guy's Hospital, London, United Kingdom, [3]Paediatric Cardiology, Evelina Children's Hospital, St Thomas' Hospital, London, United Kingdom.

6q25.3 microdeletions identified on array CGH have been reported in association with intellectual disability, acquired microcephaly, dysmorphic features, structural anomalies of the brain and non specific multiple organ anomalies. *ARID1B*, comprised in this deletion, had been identified as the potential candidate gene to explain this distinctive phenotype. Coffin-Siris syndrome (CSS) is a rare, clinically heterogeneous disorder often considered in the setting of cognitive/developmental delay and 5th finger/nail hypoplasia. Due to the clinical variability, this diagnosis can be difficult to confirm clinically and the existence of this disorder as a specific diagnosis has even been at times an issue of debate. Recently, haploinsufficiency of *ARID1B*, now known as one of the SWI/SNF chromatin-remodeling complex member, has been identified as causing CSS. Therefore the 6q25.3 deletion

distinct phenotype should be considered as CSS too.
We report on an 8 months old male, born to healthy unrelated parents. Complex heart malformation had been identified on antenatal scans and parents declined invasive testing. He was born with normal growth parameters. Examination revealed slight dysmorphic features comprising a hirsute forehead, down-slanting palpebral fissures, full lips, deep palmar and plantar creases and small fifth toenails. Tight aortic coarctation was associated with a small mitral valve and poor function of the lateral left ventricle wall. Brain MRI revealed hypoplasia of the corpus callosum. Array-CGH revealed a de novo 69kb deletion at 6q25.3, resulting in partial deletion of *ARID1B*. Since *ARID1B* has also been involved in childhood neuroblastoma, we will discuss about clinical management and genetic counselling implications.

Cohen syndrome (CS) is an autosomal recessive disorder, displaying intellectual disability, microcephaly, truncal obesity, retinal dystrophy and intermittent neutropenia. CS is due to mutations in the *VPS13B* gene, encoding a crucial Golgi-membrane protein. Neutropenia being very rarely described in syndromology, we hypothesized that neutropenia could be a clue to approach the pathophysiology of CS. According to studies in other congenital neutropenias, it could be due to maturation arrest of neutrophils, dysfunctions or apoptosis of mature neutrophils. We confirmed that granulopoïesis was normal in CS patients; neutrophils display normal morphology, chemotaxis, phagocytosis and generation of reactive oxygen species. Transmission electron microscopy revealed a disrupted Golgi apparatus morphology. We then isolated $CD16^+$ neutrophils from CS patients and healthy donors and showed by Annexin V-propidium iodide and Hoescht staining that CS neutrophils displayed an increased apoptosis rate compared to healthy donors. This exaggerated apoptosis was observed only in neutropenic patients, and was specific of neutrophils, as CS $CD3^+$ lymphocytes and $CD14^+$ monocytes were not affected. For most of CS patients, in contrast to healthy donors, GM-CSF had no protector effect despite normal GM-CSF serum level, receptor mRNA expression and signaling. *VPS13B* mRNA expression dramatically decreased during spontaneous apoptosis of normal neutrophils whereas mRNA expressions of 4 other genes (*ELA2, HPN3, MPO* and *LYZ*) were stable, confirming the correlation between VPS13B and apoptosis. As congenital neutropenia can result from increased endoplasmic reticulum stress, experiments are in progress to determine its involvement in CS. These results may give clue for understanding other CS features.

When transmission modifies the complexity of familial complexe rearrangements

V. Gatinois, *G. Lefort, C. Coubes, J. Puechberty, A. Schneider, S. Taviaux, M. Tournaire, M. Di Nicola, M. Girard, P. Sarda, F. Pellestor;*
Chromosomal Genetics Laboratory, CHRU, Montpellier, France.

Complex Chromosome Rearrangements (CCR) are rare events, defined by the occurrence of at least 3 chromosome breakpoints. The degree of complexity of CCRs can be very high and the related meiotic disturbances result in important chromosomal imbalance in gametes. During meiosis, crossing-overs between involved chromosomes can modify the complexity of the rearrangement with numerous possibilities of chromosomal imbalance in gametes. We report 2 familial cases in which meiotic events result in a new chromosome rearrangement. Chromosomal analyses were performed using classical cytogenetic procedures (R- and G-banding) and various FISH techniques (chromosome painting and array-CGH). In addition, we developed 2 additional methodological approaches, the „chromosome walking" and Array Painting, for the breakpoint studies. In our first case, karyotyping was done following the discovery of a multiple malformation syndrome on ultrasound examination. The fetal karyotype showed an unbalanced CCR with 3 breakpoints. Subsequent analysis of the mother's chromosomes revealed an apparently balanced CCR with 4 breakpoints. For the second case, a male carrier of a simple reciprocal translocation inherited through his mother fathered a girl with a more complex rearrangement involving a third chromosome. In the 2 cases, a re-building of the initial rearrangement occurred through meiotic recombinations, giving rise to simpler or more complicated karyotypes. For both cases, breakpoint studies led to an understanding of the involved mechanisms underlying the simplification or complexification of the parental rearrangement.

P02.049

Prenatal diagnosis of paternal uniparental isodisomy of chromosome 14 (patiUPD14) with chromosomal micro-array (CMA) in a fetus with multiple congenital abnormalities.

A. Bazin[1], *D. Trost*[1], *P. Kleinfinger*[1], *L. Lohmann*[1], *B. Bessières*[2], *F. Guis*[3];
[1]*Laboratoire Cerba, St Ouen l'Aumone, France,* [2]*Hôpital Necker Enfants Malades, Paris, France,* [3]*Institut Mutualiste Montsouris, Paris, France.*

Case report
The patient, a 43 years old primigravid woman was referred at 12 weeks of gestation for prenatal diagnosis because an ultrasound scan identified an increased nuchal translucency (3.8 mm, CRL 59 mm). The karyotype on uncultured chorionic villi was normal: 46,XX (15 cells, RHG banding). There were no particularities in the familial history nor consanguinity.
CMA was performed with PrecytoNEM (derived from Agilent 60K, resolution 400 Kb) and didn't show any unbalanced abnormality.
At 23 WG, a subsequent ultrasound showed multiple abnormalities. There was a polyhydramnios, a generalized oedema, dysmorphic features with long filtrum, small rounded ears and prefrontal oedema, a very short femur length (<1° percentile) in contrast with the body weight estimated at the 83° percentile, an abdominal wall eventration and large feet with abnormal hallux implantation.
Amniocentesis was performed to exclude a tetrasomy 12p (Pallister-Killian syndrome) possibly undiagnosed on chorionic villi because of a chromosomal feto-placental discrepancy: the karyotype was again normal and the Fish analysis ruled out tetrasomy 12p. The parents opted for termination of pregnancy after counselling about the poor prognosis of the fetal malformations. Post-mortem examination evoked patUPD14.
The CMA with Affymetrix CytoScan (SNP-array) on the amniotic fluid again did not show any pathogenic CNV but exhibited a complete isodisomy for chromosome 14. Paternal iUPD14 was confirmed by parental microsatellite segregation.
Discussion
We discuss the different underlying causes for patUPD. Although it's an uncommon finding in fetal malformations, SNP's CMA allowing both UPD and CNV detection may be helpful in such conditions.

Impaired embryogenesis (plurimalformative syndromes) as a leading cause of altered anthropometric parameters in patients with congenital anomalies of the kidney and urinary tract

C. Daescu[1,2], *O. Marginean*[1,2], ***M. Puiu***[2,2], *A. Craciun*[1,2], *T. Marcovici*[1,2], *A. Militaru*[1,2], *O. Belei*[1,2], *D. Chiru*[1,2], *C. Pienar*[2], *A. Chirita-Emandi*[2];
[1]*"Louis Turcanu" Emergency Hospital for Children Timisoara, timisoara, Romania,*
[2]*„Victor Babes" University of Medicine and Pharmacy, Timisoara, Romania.*

Introduction: Congenital anomalies of the kidney and urinary tract (CAKUT) comprise all the defects that appear during the embryonic development of the kidney and lead to altered renal structure and/or function. Material and method: We studied 209 children with CAKUT admitted to our Nephrology Department between January 1st 2004 and December 31st 2009. The mean age of patients at admission was 7.12 ± 5.88 years. We assessed the anthropometric status of our lot by calculating the Z score for weight and height, we evaluated CAKUT that were associated with malnourishment, and how renal failure influenced height and/or weight. Results: Distribution of the patients according to sex and renal anomaly showed that the dia-

gnosis of certain CAKUT is more frequent in the female sex: congenital hydronephrosis (17.22%), vesicouretheral reflux (14.35%), abnormal kidney position (10.52%), renal dys/hypoplasia (7.17%), double collecting system (6.69%), renal agenesis (4.78%), only the ureteropelvic junction obstruction (11.96%) was more frequent in the male sex. Analysis of anthropometric indices enabled us to obtain the weight and height Z score histogram, demonstrating the group's uniformity and highlighting the cases (5.26%) with 2nd and 3rd stage malnourishment that were associated with:(a) the following CAKUT: vesicoureteral reflux, renal dysplasia, neurogenic bladder, bladderepispadias extrophy syndrome, Prune-Belly syndrome, double collecting system and polycystic kidney disease; and (b) renal failure stages 4 and 5. Conclusion: Two factors were implicated in altered anthropometric parameters in our patients: impaired embryogenesis (plurimalformative syndromes) and chronic renal failure.

Is Arg5 in HOX_DNA binding domain of *HOXB1* hot spot for congenital facial paralysis mimicking Moebius syndrome?

O. Z. Uyguner[1], *H. Ozgur*[1], *U. Altunoglu*[1], *G. Toksoy*[1], *S. Basaran*[1], *H. van Bokhoven*[2], *H. Kayserili*[1];
[1]*Department of Medical Genetics, Istanbul Medical Faculty, Istanbul University, Istanbul, Turkey,* [2]*Department of Human Genetics, Radboud University, Nijmegen Medical Centre, Nijmegan, Netherlands.*

Congenital facial paralysis (CFP) and Moebius syndrome (MBS; MIM 157900) are highly sporadic, formulating **classical** gene identification **algorithms** difficult, assigning candidate gene approach compatible. Mutant mice for *Hoxb1* were long before reported to present features of facial nerve defects, resembling MBS, only very recently associated with human phenotype. Currently, homozygous c.619C>T in *HOXB1* revealed in the two CFP affected individuals from two different families, both from the same geographic origin, altering arginine to cysteine at 207 (p.arg207cys) corresponds *arg*5 residue of the HOXB1 homeodomain.
We have screened our cohort of 33 sporadic MBS and CFP patients for mutation on *HOXB1* and identified homozygous c.620G>A in one consanguineous family. Alteration changes the same neutral-polar arginine, via second nucleotide, resulting to basic-polar histidine (p.arg207his). Clinical investigation of our case presented left esotropia, right flattened/broad nasal bridge, external ear defects, high arched palate, bilateral cranial nerve VII dysfunction, diagnosed as CFP. We further screened *HOXB1* in 56 DNA samples of MBS cases, referred to us from Radbound University Nijmegen-Holland, none found to carry any pathological alteration. It is surprising that, such a rare disorder with three only identified mutation striking the same conserved amino acid, delegating *arg*5 the achilles of HOXB1 protein. Up to date, out of 267 families with MBS or with the facial weakness, component of MBS (177 from Webb et al.2012, 56 from Nijmegan group and 34 from our center), only three reported to carry mutations in *HOXB1* gene, figuring the prevalence of *HOXB1* mutation frequency to be 1.12%.

Congenital heart defects in recurrent reciprocal 1q21.1 deletion and duplication syndromes: Rare association with pulmonary valve stenosis

A. De Luca[1], *M. C. Digilio*[2], *L. Bernardini*[1], *F. Consoli*[1], *F. R. Lepri*[2], *M. G. Giuffrida*[1], *A. Baban*[2], *C. Surace*[2], *R. Ferese*[1], *A. Angioni*[2], *A. Novelli*[1], *B. Marino*[3], *B. Dallapiccola*[1];
[1]*Mendel Institute, Casa Sollievo della Sofferenza Hospital, IRCCS, Rome, Italy,* [2]*Medical Genetics, Cytogenetics and Pediatric Cardiology, Bambino Gesù Pediatric Hospital, IRCCS, Rome, Italy,* [3]*Pediatric Cardiology, Department of Pediatrics, Sapienza University, and Eleonora Lorrillard Spencer Cenci Foundation, Rome, Italy.*

Microdeletion 1q21.1 (del 1q21.1) and the reciprocal microduplication 1q21.1 (dup 1q21.1) are newly recognized genomic disorders, characterized by developmental delay, dysmorphic features and congenital malformations. Congenital heart defect (CHD) is a major feature of del 1q21.1, and has been occasionally reported in dup 1q21.1. We report here a family segregating del 1q21.1 in 3 members. Two of the affected family members had CHD, including the proband with syndromic atrial septal defect, pulmonary valve stenosis (PVS), and muscular ventricular septal defects, and the maternal uncle with non-syndromic PVS. This finding prompted investigation of the role of recurrent rearrangements of chromosome 1q21.1 in the pathogenesis of PVS. We gathered 38 patients with PVS (11 syndromic and 27 non-syndromic), and searched for genomic rearrangements of 1q21.1. A dup 1q21.1 was detected in a single sporadic non-syndromic patient. Review of the CHDs in published del 1q21.1 and dup 1q21.1 subjects showed a great heterogeneity in anatomic types. In conclusion, the present family illustrates recurrent CHD in del 1q21.1, expressing either as syndromic in one family member or as non-syndromic in the another one. The spectrum of CHDs associated with del 1q21.1 and dup 1q21.1 can occasionally include PVS.

P02.053

A second case of Cornelia de Lange Syndrome with mutation in the SMC3 gene confirms this gene as a cause of the syndrome.

F. J. Ramos[1,2], *M. Gil-Rodríguez*[1], *L. Bomme-Ousager*[3], *M. A. Deardorff*[4,5], *C. Baquero*[1], *M. Kibaek*[3], *B. Puisac*[1], *M. Hernández-Marcos*[1], *E. Teresa-Rodrigo*[1], *E. Queralt*[6], *F. J. Kaiser*[7], *P. Gómez-Puertas*[8], *I. D. Krantz*[4,5], *J. Pié*[1];
[1]*University of Zaragoza Medical School, Zaragoza, Spain,* [2]*Hospital Clinico Universitario „Lozano Blesa", Zaragoza, Spain,* [3]*Odense University Hospital, Odense, Denmark,* [4]*The Children's Hospital of Philadelphia, Philadelphia, PA, United States,* [5]*The University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States,* [6]*Institut d'Investigacions Biomèdicas de Bellvitge (IDIBELL), L'Hospitalet de LLobregat, Barcelona, Spain,* [7]*Institut für Humangenetik Lübeck, Universität zu Lübeck,, Lübeck, Germany,* [8]*Center of Molecular Biology, Cantoblanco, Madrid, Spain.*

Cornelia de Lange syndrome (CdLS) is an inherited disorder characterized by facial dysmorphism, growth and cognitive impairment, limb malformations and multiple organ involvement. Mutations in five genes that encode components of cohesin complex account for 70% of patients with CdLS-like phenotype. However, in one of the genes, *SMC3*, only one mutation in a mildly affected adult has been reported.
Here, we report on the second novel mutation in the SMC3 gene in a boy with CdLS. He showed classical CdLS phenotype with typical facial dysmorphism, multiple musculoskeletal anomalies, hirsutism and severe developmental delay. He also had myopia, moderate hearing loss, mild pulmonary and supravalvular aortic stenosis, pyloric stenosis, vertebral anomalies, and gastroesophageal reflux disease. Molecular analysis identified a *de novo* mutation in exon 22 (c.2494_2499del) of the *SMC3* gene, which predicted in-frame deletions of two residues highly conserved and mapped to the C-terminal coiled-coil domain, p.(Leu832_Asn833del). Structural analysis of the mutant SMC3 protein showed a serious shift in the relative position of the accompanying residues, leading to the displacement of the corresponding residues of the two antiparallel helices that form the coiled coil.
Our case demonstrates that mutations in the *SMC3* gene may cause a mild to moderate phenotype, as it has been previously reported in some patients with mutations in the *SMC1A* gene. Finally, we recommend to perform mutation screening of *SMC3* in patients with CdLS phenotype in whom no mutation is identified in the other known CdLS genes.

SNP arrays in the diagnostic strategy of corpus callosum agenesis associated with intellectual disability.

B. Keren[1,2], *M. Moutard*[3], *C. Mignot*[1], *A. Jacquette*[1], *S. Chantot-Bastaraud*[4], *P. Charles*[1], *S. Whalen*[1], *E. Fonteneau*[1], *C. Mach*[1], *M. Gérard*[5], *A. Faudet*[1], *A. Brice*[1,2], *C. Depienne*[1,2], *T. Billette de Villemeur*[6], *D. Héron*[1];
[1]*Département de Génétique, Hôpital Pitié-Salpêtrière, AP-HP, Paris, France,* [2]*CRicm UPMC Inserm UMR_S975/CNRS UMR 7225, Paris, France,* [3]*Service de Nruropédiatrie, Hôpital Armand Trousseau, AP-HP, Paris, France,* [4]*Laboratoire de Cytogénétique, Hôpital Armand Trousseau, AP-HP, Paris, France,* [5]*Département de Génétique, Hôpital Robert Debré, AP-HP, Paris, France,* [6]*Service de Neuropédiatrie, Hôpital Armand Trousseau, AP-HP, Paris, France.*

Corpus callosum agenesis is the most common cerebral malformation in patients with intellectual disability (CCA-ID) with a prevalence of 2-3%. Known genetic causes are heterogeneous and in most cases, the etiologies remain unknown.
In order to achieve a genetic diagnosis, we performed chromosome analyses on microarrays (CMA) on 51 patients with CCA-ID and no known causes. We used Illumina CytoSNP-12 SNP arrays which contain 300k probes.
We found 21 different CNVs (41%) not reported in control subjects of the Database of Genomic Variants (DGV). Among these CNVs, 8 deletions (16%) were de novo and considered to be likely pathogenic, with sizes varying

from 1,3Mb to 24Mb. No de novo duplications were found.
Moreover, 10 CNVs were also carried by healthy parents, and therefore, could not be considered as the main causes of the phenotype. We were not able to recover blood samples of the parents to verify the 3 remaining CNVs.
Thus, CMA seems to be a powerful tool in the diagnostic strategy of patients with CCA-ID and no etiological diagnosis. However, the causes of CCA-ID remain unknown in most patients. In a near future, new techniques such as exome sequencing, or massively parallel sequencing on selected genes panels, will certainly improve the detection rate of the genetic causes of CCA-ID.

Molecular Test Results of Syndromic Craniosynostosis Patients: genotype-phenotype correlations

V. Karaman, *U. Altunoglu, G. Toksoy, B. Karaman, H. Kayserili, Z. O. Uyguner;*
Istanbul Medical Faculty, Istanbul, Turkey.

Synostosis is the premature fusion of cranial sutures in the brain vault producing continued growth at the position of the open cranium suture in parallel to brain growth resulting in morphological deformation called Craniosynostosis. It is observed in 1/2100-1/2500 live births, occurring in both syndromic and non-syndromic forms and addressed in approximately 180 different syndromes. Recent studies have shown that notably in 20% of cases are caused by single gene mutations or chromosome abnormalities. *FGFR2*, *FGFR3*, *TWIST1* and *EFNB1* are listed to be the most common causative genes in craniosynostosis, though rarely involved many others like *FGFR1*, *MSX2* are already known and growing number of novel genes are intensely being identified. Mutations in *FGFR2*, *FGFR3*, *TWIST1* are involved in syndromic and lesser extent in non syndromic forms while *EFNB1* are solely recognized to be associated with Craniofrontonasal Syndrome (CFNS).
Thirty craniosynostosis patients, except CFNS, where chromosomal abnormalities were previously excluded, are recruited to our research study with their families. Our workflow will be targeted mutation screening for common genes, *FGFR2* and *FGFR3*, mutation negative patients will be subject to deletion/duplication analysis by craniofrontonasal MLPA kit, which will follow by *MSX2* sequencing and targeted mutation screening for *FGFR1*.
Our investigation is ongoing presently. We anticipate that our results will foster the acknowledged molecular diagnostic flow charts in craniosynostosis and further delineate genotype-phenotype relationship. Undefined cases will be esteemed subjects for novel gene identification by next generation sequencing.

P02.056

A new syndrome of intellectual disability, postnatal microcephaly, progressive ataxia and spasticity and hair anomalies caused by CTNNB1 haploinsufficiency.

E. Dubruc[1], *A. Putoux*[1,2], *A. Labalme*[3], *C. Rougeot*[4], *D. Sanlaville*[3,2], *P. Edery*[5,2];
[1]*Department of Genetics, Bron, France,* [2]*Neuroscience Research Centre of Lyon, Inserm U1028, UMR CNRS 5292 Claude Bernard University, Lyon, France,* [3]*Est biology and pathology Centre, Bron, France,* [4]*Neuropediatric Service, hopital Femme Mère Enfant, Bron, France,* [5]*Department of Genetics, Hopital Femme Mère Enfant, Bron, France.*

We report on a 5 ½ year-old girl patient with a new syndrome characterized by developmental delay, postnatal microcephaly, progressive ataxia and spasticity, light skin and sparse, fair hair, caused by a small de novo 3p22 microdeletion encompassing the entire genomic sequence of the gene CTNNB1. CTNNB1 encodes β-catenin which has been shown to be essential for dendritic development of postnatal neurons in vivo and is also required in the skin for the differentiation of stem cells into hair follicles. Conditional β-catenin knock out mice have brain malformations, neuronal loss, impaired craniofacial development and hair follicle morphogenesis defects, a phenotype reminiscent of that of the patient presented here. In addition, point mutations of CTNNB1 have been recently reported in 3 patients with intellectual disability, using an exome sequencing strategy. Altogether, the data presented here provide compelling evidence that haploinsufficiency of CTNNB1 in human causes a new syndrome combining intellectual disability, postnatal microcephaly, progressive ataxia and spasticity, and skin and hair anomalies.

The First Reported Surviving Patient with Skeletal Abnormalities and Craniosynostosis due to Homozygous Mutations in the *CYP26B1* Gene

J. E. V. Morton[1], *S. Frentz*[2], *S. P. Robertson*[2];
[1]*Clinical Genetics Unit, Birmingham Women's Hospital, Edgbaston, Birmingham, United Kingdom,* [2]*Department of Women's and Children's Health, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand.*

In 2011, Laue et al reported two families with a lethal syndrome of craniosynostosis and multiple skeletal abnormalities due to mutations in the *CYP26B1* gene which encodes the retinoic acid-degrading enzyme CYP26B1.
We present a 22 year old female who is the first child of consanguineous parents. She was born with craniosynostosis involving the coronal and lambdoid sutures, together with limited elbow extension and finger contractures. She was thought to have hypoplastic external genitalia. CT scan of the head showed complex craniosynsotosis with a large unossified area of skull and multiple craniolacunae along the fused lambdoid sutures and in the occiput. Urinary steroid profile was normal. An initial diagnosis of Antley Bixler syndrome was made. Early milestones were normal, but she later had moderate developmental delay. She attended a school for moderate learning disabilities, and has since studied life skills at college. She is currently seeking employment and hopes to live independently. She menstruates normally. She has had one fracture, following a fall, but no other fractures. She has bilateral conductive hearing loss and has bone anchored hearing aids.
CYP26B1 analysis showed novel homozygous c.1303G>A (p.Gly435Ser) mutations. Both parents were confirmed as heterozygotes.
This patient is only the third reported case worldwide and the only case to survive beyond infancy. The diagnosis is important because it allows accurate genetic counselling and may have implications for on-going management since continued elevated retinoic acid may lead to decreased bone mineral density.

Insulin-dependent juvenile-onset diabetes may occur in the context of rare syndromic presentations suggesting monogenic inheritance rather than common multifactorial autoimmune type 1 diabetes. We report the case of a Lebanese patient diagnosed with juvenile-onset insulin-dependent diabetes presenting ketoacidosis, early onset retinopathy with optic atrophy, hearing loss, diabetes insipidus, epilepsy, and normal weight and stature, who later developed insulin-resistance. Despite similarities with Wolfram syndrome, we excluded the *WFS1* gene as responsible for this disease. Using combined linkage and candidate gene study, we selected *ALMS1*, responsible for Alström syndrome, as a candidate gene. We identified a novel splice mutation in intron 18 located 3 bp before the intron/exon junction (IVS18-3T>G), resulting in exon 19 skipping and consequent frameshift generating a truncated protein (V3958*fs*3964X). Alström syndrome is a rare genetic disorder characterized by retinal degeneration, deafness, truncal obesity, short stature, type 2 diabetes and insulin resistance. The patient's clinical presentation significantly differed from typical Alström syndrome by the absence of truncal obesity and short stature, and by the presence of ketoacidotic insulin-dependent diabetes from onset, optic atrophy and diabetes insipidus. Our observation broadens the clinical spectrum of Alström syndrome and suggests that *ALMS1* mutations may be considered in patients who initially present with an acute onset of insulin-dependent diabetes. Our study outlines the value of alternative strategies targeting patients who do not present the typical disease manifestations, in order to identify new mutations responsible for variant presentations of the disease.

Does epigenetics contribute to the phenotypic variability in the DiGeorge syndrome

C. Badja[1], *M. Artufel*[1], *M. Deveze*[1], *E. Barruet*[1], *C. El-yazidi*[1], *A. Tasmadjian*[1], *B. Binetruy*[1], *N. Philip*[1,2], *F. Magdinier*[1];
[1]*Laboratoire Genetique Medicale et Genomique Fonctionnelle, UMR S_910,Aix-Marseille Universite, inserm. Faculte de Medecine de la Timone., Marseille, France,* [2]*Service de Genetique Medicale, Hopital de la Timone Enfants, Marseille, France.*

The 22q11 deletion syndrome (22q11DS), also known as velocardiofacial (VCFS) or DiGeorge (DGS) syndrome, is a common microdeletion syndrome in human, occurring with a prevalence of one in 4000 live births. Phenotype is highly variable among patients, independentely of the size of the deletion. Symptoms include congenital heart defects, atypical face appearance, cleft palate, hypocalcemia, immunodeficiency due to thymus aplasia or hypoplasia and cognitive and behavioral abnormalities.
The deletion results from non-allelic homologous recombination during meiosis and involves highly homologous sequences called Low Copy Repeats (LCRs). Approximately, 87% of patients carry a 3-Mb deletion, known as the Typically Deleted Region (TDR). In 8% a smaller deletion of 1.5-Mb is observed, with the same clinical signs, delimiting the 22q11DS minimal DiGeorge Critical Region (DGCR).
The involvement of epigenetic mechanisms has never been described in the DiGeorge syndrome. We hypothesize that epigenetic changes at the site of recombination, inside and outside of the TDR may play an important role in this pathology and could contribute to phenotype variability. We wish to determine the impact of haploinsuffciency of different genes deleted by the microdeletion such as HIRA and DGCR8 at early differentiation stage using induced pluripotent stem cells derived from patients. More specifically, we will investigate their role during the neuronal differentiation in order to understand their contribution to the mental manifestation of DGS.
Preliminary results will be presented and discussed.

Down Syndrome associated with neonate infectious pathology

M. Boia[1], *D. Iacob*[1], *A. Manea*[1], *I. Andrei*[2];
[1]*University of Medicine and Pharmacy Timisoara, Timisoara, Romania,* [2]*Emergency Children Hospital ,'L.Turcanu", Timisoara, Romania.*

Introduction: The Down syndrome represents a complex and interdisciplinary pathology during the infant period, and even more so for the neonate.
Aim: The authors are set to analyze the pathology associated with Down syndrome, that lead to increase in hospitalization, complications, as well as the immediate and long term prognosis of the patients.
Material and method: The study took place in the our Department over a four year period. 36 patients were included, with clinical characteristics associated to specific caryotype alterations: trisomy 21 in 34 children (94,44%) and only 2 cases (4,46%)with mosaicism.
Results: The study group contained 22 neonates with gestational age below 37 weeks and 12 full term neonates, 77.77% presenting intrauterine growth retardation.
The pathology associated was: ventricular septal defect - 44.44%, atrial septal defect - 19.44%, atrio-ventricular canal defect - 16.66%, musculoskeletal malformations (congenital foot deformity - 30.55% cases, polydactyly - 8.66%, syndactyly - 5.55%).
All patients presented feeding deficit, absence of sucking reflex - 72.22%, suck-swallow incoordination.
Neonatal sepsis occurred in 36.11%, infectious pneumonia - 16.66%, ulcero-necrotic enterocolitis - 11.11%. In 16 cases (44.44%) with gestational age below 32 weeks, and birth weight below 1500g the evolution was slow, with hospitalization between 45-60 days, and 3 cases (8.33%) deceased with associated pathology: heart malformations, neonatal sepsis and ulcero-necrotic enterocolitis.
Conclusions: Extreme prematurity associated with cardiac or digestive malformations, and/or neonatal sepsis represented the major cause of death.
In the absence of associated infectious pathology the evolution was favorable, requiring fewer days of hospital care.

A corepressor gene mapping to chromosome 21 affects mitochondrial function in Down syndrome fetuses

A. Izzo[1], *R. Manco*[1], *T. De Cristofaro*[2], *R. Scrima*[3], *F. Bonfiglio*[1], *G. Cali*[2], *A. Conti*[1], ***L. Nitsch***[1];
[1]*University Federico II, Napoli, Italy,* [2]*Institute of Experimental Endocrinology and Oncology, Napoli, Italy,* [3]*University of Foggia, Foggia, Italy.*

The upregulation of chromosome 21 (Hsa21) genes causes the downregulation of several nuclear-encoded mitochondrial genes (NEMG) in heart tissue of human fetuses with Down syndrome (DS). We investigated the consequences of NEMG downregulation on the mitochondrial function in trisomic human fetal fibroblasts (DS-HFF).
Together with the upregulation of Hsa21 genes and the dysregulation of mitochondrial genes in DS-HFF we found an impairment of the mitochondrial function characterized by decreased respiratory activity, enhanced ROS production, increased levels of intra-mitochondrial calcium and abnormal cristae morphology. The mitochondrial dysfunction was more pronounced in fibroblasts derived from cardiopathic trisomic fetuses suggesting that an altered bioenergetics background might induce a more severe DS phenotype.
To unravel the molecular mechanisms underlying the mitochondrial dysfunction we focused on the transcriptional coactivator PGC-1α, which controls the expression of several NEMG, and on its repressor RIP140, which maps to Hsa21 and is known to affect oxidative metabolism and mitochondrial biogenesis. We found that PGC-1α was downregulated while RIP140 was upregulated in all independent DS-HFF cultures we tested. RIP140 silencing in DS-HFF caused a time- and siRNA concentration-dependent increase of PGC-1α expression and the decrease of ROS production.
These findings suggest that the upregulation of the Hsa21 gene RIP140 contributes to the mitochondrial dysfunction observed in DS and have potential therapeutic implications since drugs affecting the RIP140-PGC1α pathway might rescue the impaired mitochondrial phenotype.

Exome sequencing identifies a novel *EP300* frame shift mutation in a patient with features reminiscent of Cornelia de Lange syndrome

M. M. Khalifa[1], *S. A. Woods*[1], *H. B. Robinson*[1], *D. Agamanolis*[1], *L. J. Kohler*[2], *G. George Sterbenz*[2];
[1]*Akron Children's Hospital, Akron, OH, United States,* [2]*Summit County Medical Examiner's Offices, Akron, OH, United States.*

Rubinstein-Taybi syndrome (RTS) and Cornelia de Lange syndrome (CdLS) are genetically heterogeneous multiple anomalies syndromes, each has a distinctive facial gestalt. Two genes (*CREBBP* and *EP300*) are known to cause RTS and five genes (*NIPBL, SMC1A, SMC3, RAD21* and *HDAC8*) have been associated with CdLS. A diagnosis of RTS or CdLS is molecularly confirmed in only 65% of clinically identified cases. This suggests that other causative genes must exist for both conditions. In addition, although *EP300* and *CREBBP* encode homologous proteins and perform similar functions, only eight patients with *EP300* mutations have been reported. This suggests that RTS due to *EP300* could be escaping clinical recognition.
We report on a child with multiple congenital abnormalities and intellectual disability whose complex phenotype is highly reminiscent of CdLS. However, no mutations in CdLS genes were identified. Rather, a novel *EP300* mutation was found on whole exome sequencing.
Possible links between *EP300* and genes causing CdLS are evident in the literature. *EP300* and *HDAC8* are involved in the regulation of p53 transcriptional activity. In addition, p300 and other chromatin associated proteins including NIPBL, SMCA1, SMC3, have been found at enhancer regions in different cell types. This suggests that *EP300* and CdLS-related genes might be involved in a shared pathway, and their phenotypic effects might overlap.
As whole exome sequencing becomes more widely utilized, we will likely have a better understanding of the diverse phenotypes associated with *EP300* mutations. In the meantime, our findings suggest that EP300 is likely another candidate gene for CdLS.

Poma Hospital, Mantova, Italy,* [6]*Pediatric Clinic, Nis, Serbia,* [7]*Aghia Sophia Children's Hospital, Athens, Greece,* [8]*Sapienza University, Rome, Italy,* [9]*University of Istanbul, Istanbul, Turkey.*

We analysed the clinical phenotypes, evolution, and genetics of a large family presented through a single proband who suffered increasingly from jerks in her jaw especially when speaking in front of the classroom and who appeared to be photosensitive, both clinically and in EEG recordings. Speaking provoked this phenomenon, and it was not present on awakening. We ascertained eighteen family members of whom eight had either similar jaw or limb jerks. Nine family members (including the eight affected by epilepsy) showed photosensitivity in the EEG in all but two younger cases (14 and 24 yrs respectively), and this biomarker was (still) present at older age (average 55; range 50 - 58 years). We performed a linkage scan using PPR as affection status and detected complete segregation for four chromosomal regions. The proband was then investigated by Whole Exome Sequencing, which identified 4 novel, predicted damaging mutations in different genes, all located in one of the four linkage peaks. An Arg267Cys mutation in the SCNM1 gene was carried in heterozygous state in all photosensitive family members. The gene regulates splicing of voltage gated ion channels and the mutation indeed affected the level of splicing of the SCN1A splice variant that was also carried by 7 of the affected family members. No other SCNM1 mutations were found in unrelated PPR European patients, suggesting that SCNM1 is a private mutation of this family and may be causing this unique combination of phenotypes.

Esophageal Atresia (EA) with or without Tracheo-Esophageal Fistula (TEF) are common congenital anomalies whose cause is unknown in over 90% of affected patients. EA/TEF can be present either as an isolated defect or in association with other developmental defects: e.g. as one of the core features of the VACTERL (Vertebral, Anal, Cardiac, TEF, Renal and Limb anomalies) association. The hypothesis that genetic defects contribute to both EA/TEF and VACTERL etiology is supported by the fact that EA/TEF is a variable feature of several known monogenetic syndromes. Among these possible defects are Copy Number Variations (CNVs). As de novo CNVs can help to identify causal genes or affected biological pathways, the recurrence of unique and rare inherited CNVs may, in combination with other factors, predispose for the development of EA/TEF and other features of the VACTERL association. We therefore profiled 255 affected individuals with SNP-arrays. All had one or more large CNV, most of them were known polymorphisms. We observed six unique loci with a de novo CNV: 4p15, 4q35, 5q11, 6q23, 7p22 and 8q13. We also identified over 300 inherited CNVs which were either absent or uncommon in published control cohorts and our in-house database. Interestingly, 45 of these inherited variants were recurrent in our patient cohort. Ingenuity Pathway Analysis revealed enrichment of several biological functions including embryonic and digestive tract development. Using our genome-wide approach we identified several loci that may impact biological pathways disturbed in EA/TEF or VACTERL association patients.

Ospedali Civico-Di Cristina-Benfratelli, Palermo, Italy,* [5]*San Gerardo Hospital, Monza, Italy,* [6]*Santobono-Pausilipon Hospital, Napoli, Italy,* [7]*University of Padova, Padova, Italy.*

Fanconi Anemia (FA) is a rare genetic disorder of hematopoiesis where 15 complementation groups have already been described. Previous studies of FA genes mutations revealed high heterogeneity and interpopulation differences but an extensive analysis has not be documented in Italian population. In this work we characterized 104 consecutive Italian patients with a suspected clinical diagnosis of FA. Using a strategy based on complementation and Western blot analyses in lymphoblast cell lines, we defined candidate genes for the mutation screening. This allows us to detect 178 mutant alleles and to identify 94 families with mutations in the FANCA (81), FANCG (9), FANCD2 (2), FANCB (1) and FANCC (1) genes. Consistent with the wide spectrum of mutations already reported for FA, we identified 39 novel mutations that were almost all "private". Regarding FANCA, we detect 15 (11,1%) intragenic deletions. Western blot analyses show that in all cases with al least one missense mutation the FANCA protein is stably expressed. Moreover, in cell lines with a defective FANCG, the expression of the FANCA protein was always reduced consistent with the stabilizing effect of FANCG on FANCA. Eleven patients with negative DEB test but a strong FA suspicion resulted to be hematopoietic mosaics. In conclusion this approach led to the identification of FA mutations in the majority of cases, allowing us to correctly diagnose patients and to expand the spectrum of Italian mutations. It would be interesting to understand whether expression of the FANCA protein, even if mutated, correlates with a mild phenotype.

Sex reversal associated with Fanconi Anemia. A case report.

W. Ayed[1], *F. Talmoudi*[1], *W. Hammami*[1], *O. Kilani*[1], *S. Hentati*[1], *S. Abdelhak*[2], *S. Makni*[3], *A. AMOURI*[1];

[1]*Cytogenetics Department and Laboratory of Biomedical Genomics and Oncogenetics, Institut Pasteur de Tunis, Tunis, Tunisia,* [2]*Laboratory of Biomedical Genomics and Oncogenetics, Institut Pasteur de Tunis, Tunis, Tunisia,* [3]*Hôpital d'Enfants, Tunis, Tunisia.*

Fanconi anemia (FA) is one of the best defined inherited bone marrow failure syndromes. It is usually inherited as an autosomal recessive trait, but in a small subset of FA cases it can be X-linked. FA patients show marked clinical heterogeneity. Characteristic features include a progressive bone marrow failure (BMF) and an increased predisposition to malignancy. Affected individuals may also exhibit one or more congenital/developmental abnormalities including abnormal skin pigmentation, skeletal, genitourinary and gastrointestinal abnormalities.

We report a 4 year-old girl presented for thrombopenia associated with skeletal malformations referred to our Cytogenetic Laboratory of Pasteur Institute of Tunis for suspicion of FA. The main clinical feature was growth failure and radial agenesis.

Induced chromosomal breakage study was performed using mitomycin (MMC). It was carried out on peripheral blood samples obtained from the patient and a counterpart culture of control.

Cytogenetic test showed a significantly elevated level of chromosome breakage compared to controls with a percentage of unstable mitoses of 100%. According to this sensitivity to MMC, this patient was diagnosed as FA, but the RHG-banded metaphases showed a 46,XY karyotype suggesting a state of an unusual sex reversion associated with FA disorder.

As our knowledge, this is the first reported case with a 46,XY girl associated with FA.

Clinical and genetic study of Brazilian patients with fetal alcohol spectrum disorders

G. Antonialli, B. Coprerski, R. Minillo, M. MIGLIAVACCA, D. Brunoni, ***A. B. Perez****; UNIVERSIDADE FEDERAL DE SÃO PAULO, SÃO PAULO, Brazil.*

Introduction: The teratogenicity of alcohol comprises a spectrum of anomalies known as Fetal Alcohol Spectrum Disorders - FASD; the most severe phenotype is the Fetal Alcohol Syndrome. Objectives: 1) Study patients with FASD according to the Washington Criteria Diagnosis; 2) Establish the frequency of the polymorphisms of the genes of the enzymes ADH (ADH1B*3, ADH1B*3, ADH1C*2) and ALDH (ALDH2*2) in FASD patients; 3) Compare the FASD patients genotype to the control group. Results: 28 Brazilian patients aged 11 months to 17 years were evaluated according to the Washington Criteria protocol: 35,7% (10 patients) were classified in the A category; 32,1% (9 patients) category C ; the remaining patients were classified in the categories E, F, H and J. The distribution of the polymorphisms were: ADH1B*2: genotype ADH1B*1/1 85,19% and ADH1B*1/2 14,81%. ADH1B*3: genotype ADH1B*1/1 52,17%, ADH1B*1/3 43,48% and ADH1B*3/3 4,34%. ADH1C*2: genotype ADH1C*1/1 65,38%; ADH1C*1/2 19,24% and ADH1C*2/2 10,89%.ALDH2*2: genotype ALDH2*1/1 98,02% and ALDH2*1/2 15,38. There were no significant differences in the distribution of genotypes ADH1B*2 and ALDH2*2 between patients and the Brazilian population. The ADH1B * 3 allele was significantly more frequent among patients (p<0,001) and the ADH1C * 2 allele was significantly less frequent among patients (p=0,0058) compared to the healthy Brazilian population. Conclusion: Although it is a small sample, we may suggest that the ADH1B * 3 allele may be a risk factor and the ADH1C * 2 allele a protective factor to the Fetal Alcohol Spectrum disorders in the Brazilian population. Sponsor: FAPESP 2011/08960-8

New Italian patient with Filippi syndrome: a rare condition of unknown genetic origin

G. Vitiello*[1], A. Lo Castro[2], C. Galasso[2], P. Curatolo[2], G. Novelli[3], F. Brancati[1];*
[1]Medical Genetics Unit, Policlinico Tor Vergata University Hospital, Rome, Italy, [2]Department of Neuroscience, Child Neurology and Psychiatry Unit, Tor Vergata University, Rome, Italy, [3]National Agency for the Evaluation of Universities and Research, ANVUR, Rome, Italy.

Filippi syndrome is a very rare condition described so far in no more than 30 patients. The most likely way of inheritance is autosomal recessive but the molecular defect is still unknown.
We describe a 12-year-old girl, first child of non-consanguineous healthy parents, born at term after uncomplicated pregnancy. She has typical facial dysmorphism including deep-set eyes, synophrys, broad nasal bridge, thin alae nasi, thin upper lip and prognathism. Her ears are small with prominent helix. Bilateral syndactyly of fingers 3-4 (including osseous) and toes 2-3 was evident. Growth is constantly delayed with short stature (-3SD) and postnatal microcephaly, while cognitive and speech delay is in the moderate range. Ectodermal features included abnormal teeth, hypodontia and thin hair. Additional features included congenital heart defects (Ebstein's anomaly and inter-atrial septal defect) and generalized epilepsy responsive to drugs treatment.
We matched her clinical characteristics with those of 26 patients reported in the literature with Filippi syndrome and noticed a broad overlap with a restricted group of them (n=20), including the first reported patients with this condition. Tentative diagnostic criteria for Filippi syndrome are proposed: IUGR/postnatal growth deficiency (including microcephaly), typical facial dysmorphism, syndactyly of fingers and toes (mainly involving fingers 3-4 and toes 2-3) and cognitive impairment with speech delay. Ectodermal defects and abnormal genitalia support the diagnosis.
The identification of a homogeneous group of patients sharing features of Filippi syndrome will ease genetic investigations aimed at the identification of the disease-causative gene(s).

Mutations in FLNA cause different disorders. Report of two novel mutations and associated phenotypes

J. Pilch*[1], S. P. Robertson[2], T. Morgan[2];*
[1]Department of Child Neurology, Medical University of Silesia, Katowice, Poland, [2]Department of Paediatrics and Child Health, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand.

Filamin A is an actin binding protein, a product of X-linked FLNA gene. It interacts with multiple cellular components including intracellular signalling molecules, channels, receptors and transcription factors. The protein plays an important role in stabilisation of cytoskeleton, cell signalling, adhesion, migration, transcription and organ development. Mutations in FLNA resulting in a loss-of-function cause defective neuronal migration in the form of periventricular nodular heterotopia. Mutations resulting in a gain of function underlie a diversity of otopalatodigital spectrum of disorders featuring a skeletal dysplasia and various cardiac, genitourinary and intestinal malformations. To a large extent the pathogenic mechanisms leading to these phenotypes are still unresolved and new patients with different mutations allow better understanding of these processes.
We present two families with different disorders caused by mutations in FLNA. In one family mother and daughter both developed epilepsy during childhood associated with bilateral prominent periventricular nodular heterotopia. In the second family a 15-years-old boy was diagnosed with frontometaphyseal dysplasia without inner organ abnormalities. Sequencing of FLNA confirmed presence of missense mutations. In the former we found both affected individuals were heterozygous for c.82A->G. In the second case the proband was hemizygous for a c.745G->T mutation that predicts the substitution p.D249Y. Both are novel mutations with the first being predicted to substitute an initiator methionine residue for one transcript of FLNA. The second mutation predicts the substitution of a residue in the actin binding domain in a manner very similar to other FMD causing variants. Functional investigations in both families are ongoing.

P02.070

Isolated urogenital malformations caused by novel biallelic FRAS1 mutations

D. Niedrist*[1], K. Steindl[1], P. Joset[1], P. Bode[2], J. Wisser[3], A. Rauch[1];*
[1]Institute of Medical Genetics, University of Zurich, Schwerzenbach - Zürich, Switzerland, [2]Institute of Pathology, University Hospital Zurich, Zürich, Switzerland, [3]Department of Obstetrics, University Hospital Zurich, Zürich, Switzerland.

Fraser syndrome (FS) is a rare autosomal recessive disorder characterized by cryptophthalmos, syndactyly, and urogenital malformations. So far mutations in the genes FRAS1, FREM2 and GRIP1 have been identified in humans with FS, while FREM1 biallelic mutations were reported in "bifid nose, renal agenesis, and anorectal malformations" (BNAR) syndrome and Manitoba-oculo-tricho-anal (MOTA) syndrome.
We report on two female foetuses of healthy, unrelated parents diagnosed with bilateral renal and ureteral agenesis. Additional findings were vaginal atresia and tracheobronchial forgut duplication in the first fetus and hypoplastic bladder, uterus unicornis (left side) and aplasia of the right tube and dislocation of the right ovar into the upper segment of the abdomen. This spectrum of urogenital anomalies fit well into the Fraser syndrome spectrum, but characteristic features such as cryptophthalmos or syndactyly were absent. We therefore performed exome sequencing in one fetus and revealed novel compound heterozygous FRAS1 mutations: a 2bp deletion resulting in a premature stop codon (c.1146_1147delTG) and a missense mutation affecting a highly conserved amino acid (c.2017T>G).
Since the majority of FS mutations represent premature stop mutations, we assume that compound heterozygosity with this specific missense mutation may explain the atypical phenotype in our family. Notably, single heterozygous FRAS1 and FREM2 missense mutations were recently described in unilateral non-syndromic CAKUT (congenital abnormalities of the kidney and urinary tract).
Our finding therefore expands the phenotype of biallelic FRAS1 mutations to non-syndromic congenital malformations of the genitourinary tract, which is important for prenatal diagnosis and genetic counseling.

The phenotypic spectrum of GLI3 mutations includes Greig cephalopolysyndactyly (GCPS) and Pallister-Hall (PHS) syndromes. PHS first described as a neonatally lethal condition associates hypothalamic hamartoma, bifid epiglottis, postaxial or central polydactyly, intrauterine growth retardation and anal atresia. GCPS is less severe and combines polysyndactyly of hands and feet and craniofacial features. Phenotype-genotype correlations have been found both for the location and the nature of GLI3 mutations, suggesting different roles of GLI3 during development.
Here we report on the molecular and clinical study of 71 cases from 51 families with either a GLI3 mutation (66 GCPS or PHS), or a large deletion encompassing the GLI3 gene (5 GCPS cases). Most of mutations are novel and consistent with the genotype-phenotype correlation. We describe PHS patients ranging from a mild/incomplete phenotype to severe malformations extending the phenotype to agnathia with absent oral cavity, skeletal anomalies with oligosyndactyly. GLI3 expression studied by in situ hybridisation during human development confirmed its early expression in target tissues including in pharyngeal arches, and later in mandible. Our results emphasise on the possible lethality of GLI3 mutations, extend the phenotypic spectrum of malformations to severe craniofacial and reductional limb defects and further show the overlap between PHS, SLO and OFD syndromes.

Two cases of Heterotaxy with Neural Tube Defect: Further evidence of an uncommon association

J. A. Pierre-Louis, *C. A. Campagnolo, S. Goobie;*
London Health Sciences Centre, London, ON, Canada.

Heterotaxy is a multiple congenital anomaly syndrome characterized by complex cardiovascular malformations and visceral situs anomalies. It results from failure to establish normal left-right asymmetry during embryonic development. Multiple anomalies have been reported in associated with heterotaxy; however, there have been few studies considering the relationship between heterotaxy and midline anomalies in general, and heterotaxy and neural tube defect specifically. We describe two cases, one prenatal and one pediatric, with the combination of heterotaxy and neural tube defect. At present, the genetic basis of the phenotypes in our cases is unknown. Mutations in ZIC3, which have been reported in mice with heterotaxy and NTDs, have been ruled out. These cases add support to the hypothesis that the mid-line development plays a significant role in establishing laterality and that there are common mechanisms involved in both heterotaxy and neural tube defects.

New candidate genes in holoprosencephaly: results from homozygosity mapping in six inbred families

M. de Tayrac[1,2], *M. Babron*[3,4], *C. Dubourg*[1,2], *C. Mouden*[2], *R. Bouvet*[5], *S. Gazal*[3,4], *M. Sahbatou*[6], *L. Ratié*[1], *V. Dupé*[1], *J. Mosser*[1,2,5], *S. Odent*[1,7], *V. David*[1,2];

Holoprosencephaly (HPE) is a congenital malformation of the human brain due to an imperfect division of the forebrain during early development. Multiple genetic defects have been identified as involved in this process. It is now currently admitted that HPE is a multihit pathology caused by at least two or more dysfunctional events involving at least 4 major genes (*SHH, ZIC2*, *SIX3* and *TGIF*) and 10 minor genes belonging to different signaling pathways. However, the mutations and deletions in these genes represent only 30% of HPE cases. Recessive inheritance of HPE can also be suspected in consanguineous families with intrafamilial recurrence. Homozygosity mapping was undertaken in six families with history of consanguineous marriage to search for regions harboring mutations that are identical by descent. Parents and affected children were genotyped on HumanCytoSNP-12 arrays (Illumina). We first determined the population ancestry of each family with OriginMineR [de Tayrac, ASHG 2012] to estimate their specific SNP allele frequencies. Inbreeding coefficients of affected children were estimated from their genomic data by the FEstim method [Leutenegger *et al.*, 2003]. Using the genomic inbreeding coefficient we performed homozygosity mapping without relying on the genealogical information. In parallel we detected the runs of homozygosity across the genome for each individual (PLINK). Three regions of interest were detected by both methods on chromosomes 1, 6 and 10. We applied Endeavor software to prioritize genes in these regions. One of them was previously identified by CGH array on chromosome 6 (*DLL1*) and other good candidate genes will be presented.

Molecular investigation in a group of patients with Holoprosencephaly

L. A. Ribeiro-Bicudo[1], *B. F. Gamba*[2], *A. B. Rocha*[1], *A. C. Gaspar*[1], *V. T. do Ó*[1], *A. Richieri-Costa*[1];
[1]*Hospital de Reabilitacao de Anomalias Craniofaciais, Bauru, Brazil,* [2]*Universidade Estadual Paulista, Botucatu, Brazil.*

Holoprosencephaly (HPE) is the most common forebrain developmental anomaly in humans. Classic HPE occur with a prevalence of 1 in 250 during early embryogenesis, decreasing throughout gestation to a frequency of 1 in 16000 live births. The etiology of HPE is complex, with both environmental and genetic factors being implicated. Three levels of increasing severity are described in HPE: lobar, semilobar and alobar. Another milder subtype of HPE called the middle interhemispheric variant (MIHF) or syntelencephaly, has now been recognized. In the present work we analyzed a group of 70 individuals within the spectrum of holoprosencephaly through molecular techniques. We first performed Sanger sequencing for *SHH, SIX3, TGIF* and *ZIC2* genes. Then, we performed MLPA and array-CGH. The sequencing showed mutations on *SHH, ZIC2*, and *SIX3* genes. MLPA analysis showed a deletion on *SHH* and *TGIF*, and a duplication on *ZIC2*. Array-CGH showed deletions on *SIX3* as well as in other regions of the genome. From the total of 70 individuals, 29% presented a variation. Whereas the etiology of HPE is not completely defined our data are consistent with the literature. A new study is being designed and will use Next Generation Sequencing, and bioinformatics tools to analyze genes that have not been studied that may vary in HPE.

Holoprosencephaly-diencephalic hamartoma (HDH) is a rare disorder involving a hypothalamic hamartoma (benign embryonic tumour of the hypothalamus), holoprosencephaly and various cephalic and extra-cephalic anomalies. Only a few cases of HDH have been reported, most of which are sporadic. The etiology of this syndrome remains unknown and specific causative genes have yet to be identified. We report on two siblings from a non-consanguineous Irish family with a syndrome consistent with familial HDH causing early neonatal death. Externally, both children had bilateral severe microphthalmia with a central cleft lip and cleft palate. Internally, both babies had an abnormal skull base, holoprosencephaly and a hypothalamic hamartomatous mass. One child also had cardiac anomalies. Recurrence of HDH is extremely rare, and suggests a recessive disease gene in the family described here. Diagnostic mutation screening was performed and excluded *GLI3*, *SOX2*, *STRA6*, *ROR2*, *HOXD13*, *SHH*, *ZIC2*, *SIX3* and *TGIF* as possible causative genes in this family. Whole exome sequencing of DNA from the two affected siblings and their parents has been performed. Analysis of the exome data is in progress to identify recessive variants that segregate with the multiple malformation syndrome in this family.

A case of hypomyelination - oligodontia - extrapyramidal signs - ataxia syndrome (Pol3 - associated hypomyelinating disorder)

M. A. Bulatnikova[1,2], *A. A. Vasilishina*[1,2], *A. B. Smolyaninov*[1,2], *V. I. Larionova*[1,3];
[1]*North-Western State Medical University named after I.I. Mechnikov, St.Petersburg, Russian Federation,* [2]*Stem Cell Bank Pokrovski, Medical Center Pokrovski, St.Petersburg, Russian Federation,* [3]*The Turner Scientific and Research Institute for Children's Orthopedics, St.Petersburg, Russian Federation.*

A 4-year-old girl was born to non-consanguineous Caucasian parents. Her physical and psychomotor development was normal until the age of 8 months, but moderate muscle hypotonia and slight convergent strabismus were noted by a neurologist. At 8 months of age, short periods of postural tremor of the head and hands appeared. The girl began sitting independently at about 9 months old, walking with holding at 1 year 1 month, and speaking at the age of 1 year. When she began walking, constant postural tremor of head and legs and titubation were observed. The dentition was significantly delayed and abnormal. The central incisors were unerupted for almost 4 years, and the first canine erupted when she was two. Since the age of 2 years, the patient was walking independently, but ataxia was present. She was speaking single sentences with dysarthria. At 3 y.o. strabismus increased and myopia was diagnosed. Neurological examination revealed convergent strabismus, horizontal nystagmus when she focused to the left and right, early signs of supranuclear gaze palsy - vertical nystagmus and need to lift up the head to focus on a floor. The head, hands and body postural tremor, moderate muscle hypotonia and bilateral Babinsky signs were observed. MRI demonstrated diffuse hypomyelinization with prevalence of low T2 signal from frontal lobe white matter and optic radiation. Hypomyelination and/or hypodontia syndrome is caused by mutations of POLR3A and POLR3B genes. In this case we performed a sequencing of exon 15 of POLR3B. The heterozygous mutation c.1568T>A (p.Val523Glu) was found.

Comprehensive methylation testing broadens the epigenetic and clinical description of Imprinting Disorders.

D. J. G. Mackay[1,2], *R. L. Poole*[1,2], *L. E. Docherty*[1,2], *A. Al Sayegh*[3], *A. Caliebe*[4], *C. L. S. Turner*[5], *E. L. Baple*[6], *E. L. Wakeling*[7], *S. E. Flanagan*[8], *A. T. Hattersley*[8], *S. Ennis*[1], *I. K. Temple*[1,9];
[1]*University of Southampton, Southampton, United Kingdom,* [2]*Wessex Regional Genetics Laboratory, Salisbury, United Kingdom,* [3]*Sultan Qaboos University Hospital, Alkoudh, Oman,* [4]*Institut für Humangenetik des Universitätsklinikum Schleswig-Holstein, Kiel, Germany,* [5]*Royal Devon and Exeter NHS Foundation Trust, Exeter, United Kingdom,* [6]*St George's University of London, London, United Kingdom,* [7]*North West London Hospitals NHS Trust, London, United Kingdom,* [8]*University of Exeter, Exeter, United Kingdom,* [9]*Wessex Genetics Service, Southampton University Hospitals Trust, Southampton, and Salisbury Hospital NHS Foundation Trust, Southampton, United Kingdom.*

Imprinting disorders (IDs) are associated with mutations and epimutations affecting imprinted genes, whose expression is restricted by parent of origin. ID diagnosis is challenging because their clinical features are heterogeneous and partially overlapping, and their underlying molecular defects include mutation, epimutation, copy number and chromosomal errors, and can be further complicated by somatic mosaicism and multi-locus methylation defects. It is currently unclear to what extent the phenotypic heterogeneity of IDs reflects their underlying molecular pathophysiology, particularly for multilocus methylation defects (MLMD). To address these issues we performed comprehensive methylation analysis of imprinted genes in 285 patients with clinical features of IDs, with or without a positive molecular diagnosis.
20 of 91 (22%) ID patients had MLMD - ie, additional imprinting anomalies independent from their primary clinical presentation - including 6/35 SRS patients (17%), 8/29 BWS patients (28%), 4/8 (50%) TND patients and 1/11 (9%) PHP1b patients.
The frequency of developmental delay was higher (67%) in MLMD than 'isolated' SRS (26%), and 5/6 SRS-HIL cases had atypical clinical features, compared with 23% of isolated SRS. Compared to 3/11 of 'isolated' BWS (hypomethylation of ICR2), 8/8 of BWS-MLMD had developmental delay ($P = 0.004$); and 6/8 BWS- MLMD had atypical congenital anomalies compared with 4/13 'isolated' BWS. While glycaemia was similar in all TND patients, congenital anomalies were more frequent in those with MLMD, as was assisted reproduction. These findings highlight the heterogeneous molecular anomalies and variable clinical phenotypes of IDs and indicate the value of comprehensive molecular investigations.

Hospital Niño Jesús, Madrid, Spain,* [4]*Servicio de Dermatología. Hospital Clínico Universitario de Salamanca, Salamanca, Spain,* [5]*Unidad Medicina Molecular. Facultad de Medicina. IBMCC-IBSAL, Salamanca, Spain.*

Incontinencia Pigmenti (IP) is a genodermatosis disease associated with mutations in NEMO gene which is situated on X chromosome. A pathogenic mutation on this gene is usually lethal in males. We have analyzed NEMO gene in two males with a suspect of IP in order to look for some alterations which could explain the altered phenotypes.
We have studied two males that present an IP phenotype. The first one (A) is less than 1 year old, the second case (B) is 20 months old. We have analyzed the 10 exons of the NEMO gene by PCR and direct sequencing.
In case A, we have observed that one of the two copies of the NEMO gene is deleted from 4 to 10 exons. In case B, we have only observed a heterozygous codon 326 deletion (exon 8 p.K325_327delK). This mutation has
not been found in his parents. The karyotypes of both patients showed alterations. In case A, a Klinefelter syndrome (XXY) was detected. In case B we observed a trisomy XXY in the 2%, a XYY in the 1% and a XXYYY in the 1% of the total cells.
We present two unusual cases of males carrying NEMO mutations. One of them carry Klinefelter syndrome with two copies of chromosome X. In patient B, the trisomy can not invalidate the possible lethal effect of the mutation found, due to the few percentage of cells with trisomy.
Therefore we can speculate that a mosaicism might explain this case.

Mosaic 8p interstitial deletion with absent nails: genotype/phenotype correlation

A. K. Kamel[1], *A. M. Mohamed*[1], *M. S. Zaki*[1], *N. A. Helmy*[1], *A. Fayez*[1], *J. G. Gleeson*[2], *M. O. Elruby*[1];
[1]*National Research Centre, Cairo, Egypt,* [2]*Department of Neurosciences and Paediatrics, Rady Children's Hospital, San Diego, CA, United States.*

The aim of this study was to correlate genotype/phenotype in interstitial deletion of chromosome 8p and to compare the sensitivity of FISH and array CGH in detection of low mosaic cell line. We reported on a male patient presented at the age of 40 days with CHD and recurrent chest infection. He was lethargic with infrequent myoclonic spasm. Patient had facial dysmorphism ,microcephaly.He suffered of CHD with VSD, ASD, pulmonary stenosis and dilated right ventricle. He had intractable convulsions, hypogenesis of corpus callosum, defects in myelination and mild reduce cerebellar size for his age. Both hands and feet showed absent nails (total anonychia) and abnormal increasing palmar and planter creases. He had a karyotype 46,XY,del(8)(p21.2p23). Both parents had normal karyotype. FISH analysis using subtelomere 8 and locus specific identifier for LPL at 8p22 revealed interstitial deletion involving (8)(p22) and presence of subtelomere 8p and 15% normal cell line. Nimblegen microarray analysis indicated 18.5Mb interstitial deletion of chromosome 8p spanning cytoband (8)(p23.2-p21.3) and involving GATA4 gene.
We concluded that a post zygotic deletion occurred in this infant, FISH analysis is a powerful tool in detection of low mosaic cell lines. The array CGH can identify precisely the break points and the exact deleted region. We suggest that the gene responsible for nail formation lies within chromosome 8p cytoband p23.2-p21.3. DNA sequencing for the other allele is recommended to delineate the cause of absent nails whether it is due to haploinsufficiency or autosomal recessive.

Growth pattern in Kabuki Syndrome

C. Schrander-Stumpel[1], *N. Schott*[1], *N. Cramers*[1], *W. Gerver*[1], *C. Fauth*[2], *K. Devriendt*[3];
[1]*Academic Hospital Maastricht, 6202AZ Maastricht, Netherlands,* [2]*Department of clinical genetics and clinical pharmacology,, Innsbruck, Austria,* [3]*Center for Human Genetics,, Leuven, Belgium.*

Kabuki syndrome is a multiple congenital anomaly/mental retardation syndrome including characteristic facial dysmorphology, developmental delay and postnatal growth retardation. Kabuki syndrome is caused by mutations in the MLL2 gene in about 75% of cases. One of the key features in individuals with Kabuki syndrome is postnatal growth restriction. However, information on the specific growth pattern of children with Kabuki syndrome is scarce. Only one Japanese report summarizes data in a growth chart (Niikawa et al., 1988). We present a limited report on growth data in a group of individuals with a genetically confirmed diagnosis of Kabuki syndrome. The data showed that postnatal growth retardation is a clinical feature in all cases. Postnatal height SDS ranged from -2,5 to 3,3 (mean -2,3) and the current height SDS ranged from -6,24 to -0,09 (mean -2,8) in all individuals. 26 (=70,3%) patients had a height SDS below -2 SD and thus fulfilled the definition of short stature. Since all Kabuki syndrome patients have a growth deflection during childhood and a growth spurt deficiency, a defect in the growth hormone/IGF-I axis is very likely. Further research is warranted to clarify the cause of this postnatal growth restriction. We hypothesize an altered body composition similar to that in children with Prader-Willi syndrome. Therefore, we will start a study including growth hormone therapy in children with Kabuki syndrome.

Distal interphalangeal joint contracture and disappearance of flexion crease in paediatric patients with Kabuki syndrome

S. Mizuno[1], *Y. Muramatsu*[1], *N. Miyake*[2], *N. Matsumoto*[2];
[1]*Central Hospital, Aichi Human Service Center, Kasugai, Aichi, Japan,* [2]*Yokohama City University Graduate School of Medicine, Yokohama, Japan.*

As orthopaedic complications of the Kabuki syndrome, scoliosis, abnormality or dislocation of the hip joint, patellar dislocation, and a shortened fifth finger have been reported. However, there has been no report on Kabuki patients with abnormalities of the finger joints. We examined the contracture, flexion angle, and flexion crease on the third and fourth fingers of 6 MLL2 mutation-positive children with Kabuki syndrome (ages, 4-13 years). The flexion angle of the DIP joint ranged from 120 to 170 degrees, with a visible limitation of flexion in 2 patients and a moderate limitation of flexion in 2 other patients. The flexion crease of the DIP joint on the third and fourth fingers was absent in 5 of the 6 patients. Radiographs of 4 patients revealed no morphological abnormality in the third and fourth fingers.
In this study, disappearance of the flexion crease of the DIP joint was observed in 5 of the 6 patients, and limitation of flexion was found in 4 patients. There was no distinctive finding in any of the other small joints. Laboratory findings during the clinical course revealed no morphological abnormality of the osteoarticular joints. Since there has been no report of a syndrome characterized by the contracture and disappearance of the flexion crease on the third and fourth fingers, we propose that the distal interphalangeal joint contracture of the 3rd and 4th finger and disappearance of flection crease are diagnostic features of Kabuki syndrome.

P02.082

Kabuki Syndrome: genotypic spectrum and genotype-phenotype correlations in a cohort of 200 KS patients.

A. D. C. Paulussen, *M. J. Blok, K. E. van Roozendaal, A. P. A. Stegmann, H. J. Smeets, C. T. R. M. Schrander-Stumpel;*
Maastricht University Medical Center, Maastricht, Netherlands.

Kabuki syndrome (KS, MIM: 147920) is a clinically recognizable syndrome of multiple congenital anomalies and mental retardation affecting approximately 1:30,000 live births. Key features are a characteristic face, growth retardation, developmental delay and additional features such as hypodontia and persistent foetal fingertip pads. Earlier, a major gene causing KS was identified through exome sequencing, reporting mutations in the histone methyl transferase (HMT) gene *MLL2* in 40-70% of KS patients. Recently deletions and mutations in a second gene *KDM6A* were identified as a rare cause of KS. In the current large cohort of >200 suspected KS patients from mostly European descent we evaluated the significance of mutations and/or deletions in *MLL2* and tested a subset of the MLL2 negative patients for the *KDM6A* gene. Several potential *MLL2* splice-site variants were assessed at the RNA level and allele-specific PCR was used to determine parental origin of some mutations. Phenotypic characteristics were compared between carriers and non-carriers as well as between the different types of mutations.

A.D.C. Paulussen: None. **M.J. Blok:** None. **K.E. van Roozendaal:** None. **A.P.A. Stegmann:** None. **H.J. Smeets:** None. **C.T.R.M. Schrander-Stumpel:** None.

P02.083

A comprehensive study on Kabuki syndrome: diagnostics, modeling, and therapy

B. Mandriani[1,2], *L. Micale*[1], *C. Fusco*[1], *B. Augello*[1], *M. Pellico*[1], *F. Zucchetti*[3], *S. Maitz*[3], *E. Biamino*[4], *M. Silengo*[4], *A. Selicorni*[3], *L. Zelante*[1], ***G. Merla***[1,5];
[1]*IRCCS Casa sollievo della Sofferenza, San Giovanni Rotondo, Italy,* [2]*University of Brescia, Brescia, Italy,* [3]*Clinica Pediatrica, Università Milano Bicocca, Milano, Italy,* [4]*University of Torino, Torino, Italy,* [5]*University of Trieste, Trieste, Italy.*

Kabuki syndrome (KS) is characterized by peculiar facial gestalt, mental retardation, and congenital multiorgan anomalies. *MLL2* is mutated in 60% of KS patients. The majority of them are *de novo* mutations, and in few cases *MLL2* exons microdeletion/duplication. A second gene for KS is *KDM6A*. For 30% of patients the underlying genetic cause remains unidentified.
We have enrolled nearly 400 KS patients; all were subjected to *MLL2* and *KDM6A* screening. In agreement with previous reports we found that about 65% have *MLL2* mutations, mainly nonsense and frameshift mutations, leading to a premature termination codon. *KDM6A* alterations were found in a very few patients. RT-PCR and direct sequencing from KS patients with *MLL2* splice site mutations showed that these variants cause aberrant splicing resulting in a truncating and not functional protein. Using a large collection of KS cell lines (skin fibroblast and EBV-immortalized lymphocytes) we showed that *MLL2* mRNAs bearing premature stop codon are degraded by the NMD contributing to MLL2 protein haploinsufficiency. The high number of protein truncation mutation suggests that a number of KS patients may benefit from a readthrough therapy that could restore the endogenous levels of MLL2 and KDM6A proteins. We tested 14 *MLL2* and 2 *KDM6A* nonsense mutations for their response to drug readthrough treatment by a reporter luciferase vector system. We found that 11/14 (79%) of analyzed *MLL2* and 1/2 *KDM6A* mutations displayed a significant level of readthrough in response to gentamicin suggesting that this strategy is effective and has important implications for therapy.

P02.084

A de novo 3.5 Mb microdeletion of 8p11 explains hypogonadotropic hypogonadism in a 19 years old male

E. Kuchinskaya;
Clinical genetics, University hospital, Linköping, Sweden.

GnRH deficiency with anosmia is characterized by absent or incomplete puberty, low or normal LH/FSH in the context of low testosterone and normal pituitary function and is known as Kallmann syndrom (KS). Mutations in the *FGFR1* gene are associated with Kallmann syndrome type 2, with and without anosmia. However, deletions of the *FGFR1* as a cause of KS have been described in only a few patients.
Here we report a case of KS in a 19 years old male due to a 3.5 Mb contigious deletion of chromosome 8p11. At 17 years he was referred for investigation due to absence of pubertal spurt. Clinical investigation revealed pubertal development in accordance to Tanner I, stature -3SD, low FSH, LH and testosterone, and normal finding on MRT. There was no effect on the testicles size after treatment with testosterone and investigation was completed with microarray analysis due to suspicion of Kleinfelter syndrome. The microarray analysis with 6.0 SNP chip (Affimetrix) revealed a 3.5 Mb deletion of chromosome 8p11.21p11.23 encompassing 35 genes. *FGFR1* was one of the deleted genes. The deletion was later shown to have arisen *de novo* in the patient. The clinical picture with anosmia, delayed skeletal age, history of cleft lip and palate and absent puberty is in agreement with the diagnosis of Kallmann syndrome.
In conclusion, deletions of the *FGFR1* gene are a rare cause of Kallmann syndrome but should be excluded in patients with Kallmann syndrome and no mutation in one of the Kallmann syndrome connected genes.

E. Kuchinskaya: None.

P02.085

Case report of a patient with KID syndrome associated with Dandy-Walker malformation and generalized contractures

S. Scheidecker[1,2], *V. Pelletier*[2,3], *Y. Alembik*[2], *D. Lipsker*[4], *M. Louha*[5], *L. Jonard*[5], *H. Dollfus*[1,3,2];
[1]*Laboratoire de Génétique Médicale - Unité INSERM U1112, 67085 Strasbourg Cedex, France,* [2]*Service de Génétique Médicale Centre Hospitalo-universitaire de Strasbourg, Strasbourg, France,* [3]*CARGO Centre de référence pour les affections rares en génétique ophtalmologique Centre Hospitalo-universitaire de Strasbourg, Strasbourg, France,* [4]*Service de Dermatologie Centre Hospitalo-universitaire de Strasbourg, Strasbourg, France,* [5]*Laboratoire de Biochimie Hôpital d'Enfants Armand Trousseau, Paris, France.*

Keratitis-Ichthyosis-Deafness (KID) syndrome is a rare congenital disorder characterized by the triad: vascularizing keratitis, skin lesions and hearing loss. Other rare manifestations have been also described such as Dandy-Walker malformation (DWM). About 100 patients have been described and most of them have *de novo* or, less frequently, inherited heterozygous mutations in the *GJB2* gene encoding connexin 26.
DWM suspected at the end of the pregnancy leading to the birth of our patient who presented with congenital ichthyosis. No ocular or hearing anomalies were noted. He developed progressively severe contractures of the upper and lower limbs. Progressively others symptoms were detected: vascularizing keratitis, deafness and enamel defect. We examined the boy aged 9 in our Center for Rare Genetic Ophthalmologic Diseases (CARGO) because of severe keratitis. Direct sequencing of the *GJB2* revealed a de novo p.D50A mutation, confirming the diagnosis of KID.
KID syndrome is defined by Keratitis, Ichtyosis and Deafness, but other rare features are described. To date, DWM was reported in 10 KID patients and initially considered as a coincidental finding rather than a real association. Some cases of lower limb contractures have been reported but seem to be much less severe compared to our patient.
The patient reported herein revealed atypical features and widened the manifestations of KID syndrome clinical spectrum. Moreover, mutation identification optimized the genetic counseling of the family and helped in the clinical care although the keratitis and contractures control remain difficult.

Kleefstra syndrome: the rediscovery of an old syndrome through array Comparative Genome Hybridization technology (array-CGH)

A. A. Syrmou[1], *M. Tzetis*[1], *K. A. Kosma*[1], *V. Oikonomakis*[1], *K. Giannikou*[1,2], *H. Fryssira*[1], *E. Kanavakis*[1], *S. Kitsiou-Tzeli*[1];
[1]*Department of Medical Genetics, University of Athens, «Aghia Sophia» Childrens Hospital,Greece, Athens, Greece, Greece,* [2]*Alexander S. Onassis Public Benefit Foundation, Athens, Greece, Athens, Greece.*

High resolution allowing the identification of Copy Number Variations (CNVs), greatly assisted the recognition of Kleefstra syndrome. Previously named 9q subtelomeric deletion syndrome (9Qstds), Kleefstra syndrome is either caused by a submicroscopic deletion in chromosomal region 9q34.4 or an intragenic mutation in the euchromatin histone methyltransferase 1 (EHMT1) gene, resulting in EHMT1 haploinsufficiency. Since the early 1990s, 85 patients have been described, of which the majority (85%) had a 9q34.3 microdeletion).
We present eight newly diagnosed patients who were referred for genetic evaluation due to developmental delay (DD), mental retardation (MR), various congenital anomalies and/or dysmorphic features. In all cases previous standard karyotype was negative. Agilent arrays 4x180k and 1x244k (>170.000 and > 236.000 probes respectively, average resolution 8.9kb) were used. The analysis revealed seven patients with an interstitial 9q34.4 microdeletion (two de novo and one maternal) ranging in size from 0.6Mb to 5.41Mb and in 5 of 7 patients comprising the EHMT1 gene. One patient had a duplication (1 Mb). Other important genes in the same area are the following: AGPAT2 (congenital generalized lypodystrophy), NOTCH1 (aortic valve disease), LHX3 (pituitary hormone deficiency with rigid cervical spine). Additional pathogenetic aberrations which were also observed in our patients (del3p14.1, del6p13.3, del8q24.3, del10q26.3, del15q11.1, del18p11.32-p11.21) might contribute to the patients' severe phenotype, acting as additional modifiers of their clinical manifestations. Alternatively the 9q34 defect acts as a modifier of the main clinical phenotype as is probably the case with the patient carrying the 9q34 duplication.

Elevated Congenital Malformations Rates and Chornobyl Ionizing Radiation in Rivne-Polissia, Ukraine

W. Wertelecki[1], *L. S. Yevtushok*[2], *S. F. Lapchenko*[3], *N. O. Zymak-Zakutnia*[4];
[1]*OMNI-Net Ukraine Birth Defects Programs, Rivne, Ukraine,* [2]*Rivne Province Diagnostic Center Medical Genetics Service, Rivne, Ukraine,* [3]*Volyn Province Territorial Children's Hospital, Lutsk, Ukraine,* [4]*Khmelnytski Perinatal Center, Khmelnytski, Ukraine.*

In 2000, population-based epidemiological surveillance of congenital malformations (CM) implementing methods and reporting data to the European network of companion registries (EUROCAT) was initiated in several provinces in Ukraine. Analysis of Rivne (R)-Volyn provinces combined 2000-2002 data and later of 2000-2006 solely R data, demonstrated elevated rates of neural tube defects (NTD) and microcephaly. An analysis of 2000-2009 R data of 145,437 pregnancy outcomes confirms the prior observations and indicates that these CM are statistically significantly more prevalent in the Rivne-Polissia (RP) region, an ecologically distinct zone (wetlands) inhabited by a population isolate (Polischuks). The RP region is among the most severely impacted zones by Chornobyl ionizing radiation (IR) in Ukraine. Analysis of stillbirths shows higher rates in RP than non-RP and higher rates than in the adjoining province to the south of R.
The rates in R of NTD, microcephaly, conjoined twins and teratomas are among the highest in Europe. All four categories of CM are prevalent among females. Surveys indicate that alcohol use by pregnant women is not a likely cause of microcephaly. Analyzes of 6026 recordings of whole body counts of incorporated IR, including from 1157 pregnant women indicate that incorporation levels are substantially higher among those residing in RP.
We conclude that the data is sufficiently robust to continue the CM surveillance and expand current international partnerships to include prospective investigations of specific teratogenic risks posed by persisting IR in RP and other teratogenic risks factors.

A novel *EFTUD2* splice mutation causing Mandibulofacial Dysostosis - Microcephaly

M. F. Smeland[1], *H. F. Riise Stensland*[1], *A. Jørgensen*[1], *U. Hehr*[2];
[1]*University Hospital of Northern Norway, Tromsø, Norway,* [2]*University of Regensburg, Regensburg, Germany.*

Mandibulofacial Dysostosis - Microcephaly (OMIM #610536) is a rare craniofacial dysostosis accompanied by microcephaly, intellectual disability and other malformations. *EFTUD2* , a spliceosomal gene, was recently identified by exome sequencing as causal of this multiple malformation syndrome in several publications. 28 cases have been published so far. All mutations are private, and all with available parental samples are *de novo*, except one. We describe a 3,5years old boy with progressive microcephaly but no structural abnormalities on cerebral MRI. He has psychomotor delay, especially expressive language delay, and walked at 36 months of age. His ears have a characteristic appearance with microtia, square ear lobes, ear fistulas and a preauricular tag present at birth. He has generalised epilepsy and unilateral hearing loss. There are no other malformations. His phenotype will be thoroughly described. *EFTUD2* sequencing revealed a heterozygous mutation in intron 25. This sequence variant has not been reported earlier, but interference with splicing is expected. mRNA analyses are in progress. Parental samples are normal, thus proven *de novo.*
New publications also link this syndrome to esophagal atresia, and a wide range of other malformations. Patients without microcephaly are also described. Importantly, *EFTUD2* mutations will be a differential diagnosis to well known syndromes in the group of craniofacial dysostoses and the oculoauriculovertebral spectre.

Marshall syndrome: A recessive form caused by *COL11A1* gene mutation

O. A. Khalifa[1], *F. Imtiaz*[1], *R. Allam*[1], *Z. Al-Hassnan*[1,2], *A. Al-Hemidan*[1], *K. Al-Mane*[1], *G. Abuharb*[1], *A. Balobaid*[1], *N. Sakati*[1], *J. Hyland*[3], *M. Al-Owain*[1,2];
[1]*King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia,* [2]*College of Medicine, Alfaisal University, Riyadh, Saudi Arabia,* [3]*Connective Tissue Gene Tests, Allentown, PA, United States.*

Marshall syndrome is a form of skeletal dysplasia due to several gene mutations. Recently, compound heterozygous mutations in the *COL11A1* gene was described in two unrelated patients as a cause of fibrochondrogenesis. Subsequently, dominant and recessive forms of fibrochondrogenesis resulting from mutations at a second locus, *COL11A2*, were also described. Mutations in these two genes along with *COL2A1*were previously reported to cause autosomal dominant forms of both Stickler and Marshall syndromes.
Here we report the first evidence that adds *COL11A1* defect as a cause of Marshall syndrome with a recessive mode of inheritance. The clinical findings in the two brothers of deafness, flat midface, myopia, and ectodermal abnormalities (patient 1) are highly suggestive of Marshall syndrome. Among their remaining five family members, the parents and 2 adult siblings were heterozygote carriers. All the four carriers had mild short stature and thick calvaria. In addition, the parents had mild mixed hearing loss. Direct *COL11A1* gene sequencing of our patients revealed a homozygous missense mutation c.2702G>A (p.Gly901Glu) in exon 35.
In conclusions, these findings expand the list of autosomal recessive genes of the clinically overlapping Stickler and Marshall syndromes to include *COL11A1*. Furthermore, it broadens the clinical spectrum of the recessive form of type XI collagenopathy to include Marshall syndrome.

Maternal consumption of clay during pregnancy: an unexpected cause of recurrent congenital microcephaly with intracranial calcifications in babies from French Guyana (pseudo-Aicardi-Goutière syndrome)

A. Verloes[1], *V. Lambert*[2], *G. Carles*[2], *S. Passemard*[1], *J. Goullé*[3], ***A. Laquerrière***[4];
[1]*Department of Genetics, R DEBRE Hospital, Paris, France,* [2]*Dept of Obstetrics and Gynecology, Regional Hospital, Saint Laurent du Maroni, French Guiana,* [3]*laboratoire de toxicologie, groupe hospitalier, Le Havre, France,* [4]*Rouen Institute for Medical Research and Innovation, School of Medicine, University of Rouen, Rouen, France.*

Eating clay („pemba") during pregnancy is a traditional behavior in the Bushinengue population living on the border of the Maroni river, in the French department of Guiana. Clay consist in aluminium silicate. It is a powerful chelator of iron, and this practice (linked to traditional medicine), is responsible for a high incidence of severe anemia of pregnancy in this area. We report on two sibs born to a pemba-eater mother. The first child was born at term with IUGR severe microcephaly. Intracranial „calcifications" were observed by ultrasound screening during the second trimester. CT scan confirmed massive radio-opaque deposits in the brain basis. The clinical diagnosis of TORCH or Aicardi-Goutières syndromes were suggested initially. The child survived with major developmental delay. At age 7y, she has an OFC of 39 cm (-10 SD) and a height of 10 cm (-4SD). CSF interferon and TORCH screening were negative. Recurrence of microcephaly during the second pregnancy lead to TOP, after diagnosis of a similar microcephaly. Neuropathological examination confirmed severe microcephaly, with extensive microcalcifications dispersed throughout the brain. Electron microscopy made it possible to visualize intraneuronal aluminium silicate deposits, resembling aluminium deposition observed in post-vaccinal myofasciitis. The most likely mechanism to explain this recurrence is an association of IUGR secondary to severe maternal anemia combined with accumulation of exogenous silicates in the neural cells. This appears to be the first description of fetal brain disruption secondary to ingested clay. The syndrome superficially mimics Aicardi-Goutières syndrome, and convey a high risk of recurrence.

P02.093

Congenital primary microcephaly and type B-like brachydactyly , a new syndrome?

A. LAVILLAUREIX, *J. Masliah-Planchon, S. Passemard, S. Drunat, A. Verloes;*
Department of Genetics and INSERM U676, robert debre hospital, PARIS, France.

We report a 10 year-old girl with primary microcephaly and brachydactyly. Microcephaly was suspected during the pregnancy by echography. At birth, at term, head circumference was 29cm (-5 SD), weight 2770g, length 50cm . Pregnancy was normal (no drug nor alcohol) and there were no perinatal problems and no feeding difficulties. She is the first child of unrelated parents none of the members of this family have brachydactyly or microcephaly.
She started walking at 8 month-old, first words were around 1 year.
She followed mainstream schooling. In 2nd grade, problems with motricity and writing fatigability were observed. Clinical examination at 8 year-old: showed a child of medium stature with generalised amyotrophy and microcephaly 41,5cm (-8 SD). Neurological examination was normal. She had facial dysmorphism with upslanted palpebral fissures and microdontia. She has bilateral brachydactyly ressembling type B of hands and feet, respecting thumbs but involving halluces, discovered at birth.
On X rays, the terminal phalanges were missing on most digits, intermediate phalanges were hypoplastic or aplastic, with anonychia and cone-shaped epiphyses. MRI revealed a brain of reduced volume but normal structure and gyration. CGH array (180 k), caryotype and mitomicyn-induced chromosome breakage test were normal.
To our knowledge it is the first described case of severe congenital microcephaly with normal IQ associated with brachydactyly and anonychia. This disorder is clinically distinct from Jawad syndrome (due to mutations in RBBP8/CTIP - currently under sequencing), which shows mental retardation and ungual hypoplasia, and Teebi anonychia-microcephaly syndrome, which has much milder anomalies.

P02.094

Evaluation of recurrent microdeletions and microduplications of 16p

A. J. Clarkson, *K. M. Abbott, C. Dunn, L. Sparnon, J. Staines, I. Simonic;*
Genetics, Cambridge University Hospitals NHS Trust, Cambridge, United Kingdom.

Chromosome 16 is rich in segmental duplications that mediate recurrent genomic rearrangements and the proximal short arm of chromosome 16 is particularly susceptible to such rearrangements. In the last few years, several patients with recurrent deletions and duplications from 16p11.2 to 16p13.11 have been described, with the 16p11.2 locus alone encompassing several distinct copy number changes.
Interestingly, the reported phenotypes within the distinct deletion and duplication regions are not consistent and the copy number changes have been observed in ‚phenotypically normal' individuals. The inconsistencies in clinical presentation and the presence of the copy number change in unaffected family members could be due to factors such as incomplete penetrance, variable expressivity or a failure to recognise subtle manifestations of the

phenotype. There is recent evidence to suggest that recurrent rearrangements such as these may be influenced by a two hit model for a neurodevelopmental phenotype, where a sequence variant is unmasked by the copy number change. Whatever the mechanism may be, this region poses a challenge for diagnostic interpretation.
Due to the diversity of published clinical features for these recurrent rearrangements and reports of asymptomatic parental inheritance, we present a retrospective evaluation of published cases and our own clinical patient data to identify the common clinical features, assist with genetic counselling and to standardise the reporting of 16p copy number changes within the diagnostic laboratory.

There are only a few descriptions of a deletion at 13q12.11. Here we report the molecular and phenotypic description of three unrelated patients with partially overlapping microdeletions at 13q12.11-q12.12.
The first patient, with the smallest, 1.55 Mb, deletion at 13q12.12, presented with moderate developmental delay, dysmorphic features, muscular hypotonia and bilateral coloboma of the iris and retina. The second patient, with larger, 3.12Mb deletion, at 13q12.11, presented with narrowed palpebral fissures, developmental delay, café-au-lait spots, small teeth, cryptorchidism and multicystic right kidney. Recently, in the same region, 2.1 Mb deletion have been described by der Kaloustian VM [2001]. His patient resembled our case but no renal defects were revealed.
The last patient presented with the most striking dysmorphic features including blepharophimosis, pronounced developmental delay, microcephaly (-4.3SD), muscular hypotonia, cardiac malformation (PDA that required cardiac surgery in the first year of life). He was suspected of Down syndrome in infancy then Coffin-Lowry, ATRX and Cohen syndromes were considered in his differential diagnosis. Application of array CGH reveled the 5.7Mb deletion at 13q12.11-q12.12 overlapping with both deletions presented in our previous two patients. He had no renal or retinal defects.
We hope that our detailed description of 13q12 deletion phenotype will contribute to the further genotype-phenotype delineation of that microdeletion.
The study was supported by MNiSW Grant No. 0605/B/P01/2009/37. Acquiring of the Roche NimbleGen microarray platform was co-financed by ERDF project POIG.02.01.00-14-059/09.

P02.096

Deletion 6q24.3-q25.1: a recognizable phenotype with facial dysmorphism, cardiac defect, loose skin and joints without cognitive impairment.

M. L. Jacquemont[1], *A. C. Tabet*[2], *H. Randrianaivo*[1], *P. Y. Robillard*[3,4], *D. Caillet*[5], *S. Drunat*[2];
[1]*Unité de Génétique Médicale, CHU la Réunion, Saint Pierre, France,* [2]*Département de Génétique, CHU Robert Debré, Paris, France,* [3]*Service de Réanimation Néonatale, CHU la Réunion, Saint Pierre, France,* [4]*Centre d'études périnatales, CHU La Réunion, Saint-Pierre, France,* [5]*Service de Cardiologie, CHU la Réunion, Saint Pierre, France.*

Interstitial deletions of the long arm of chromosome 6 are rare and associated with variable phenotype depending on breakpoints, localization and size of the deletion. From approximately sixty cases reported in the literature, only a minority have been characterized with high resolution techniques, making genotype-phenotype correlations difficult. We report a familial 6q24.3-q25.1 deletion, identified by CGH array, spanning 1.7 Mb (chr6 (hg18):148 727 249-150 400 356), transmitted from an affected father to his affected daughter. Congenital polyvalvular disease, dysplastic ears, long philtrum, thin upper lip, redundant skin, hypermobile joints in childhood, early delayed motor milestones with normal cognitive development were the most remarkable clinical features shared by both patients. Sixteen OMIM genes are included in the deleted region. One of them, the *TAB2* gene, has been recently reported to cause cardiac defect. Our patients share some clinical features with other patients previously described with partially overlapping deletions. Among them, all patients (6) analysed by CGH array present a facial dysmorphism with similar features to ours and 5 patients whose deletion encompass *TAB2* have a cardiac defect. All patients, except one familial case, have mild or moderate developmental delay. Hypermobile joints and redundant skin have only been reported twice in patients with 6q24-q25 deletion in studies where the mapping of breakpoints was not performed preventing from targeting a causative gene. This observation allows us to describe a new recognizable (6q24.3-6q25.1) microdeletion syndrome without developmental delay, characterized by dysmorphic features, congenital heart defect and loose skin and joints in childhood.

Array CGH has improved the detection of submicroscopic chromosome X imbalances such as duplications of the short arm of the X chromosome. They can result either from an intrachomosomal rearrangement of the X chromosome or from an unbalanced translocation between an X chromosome and an autosome or with a Y chromosome. In 2009, Giorda et al. identified an inherited or de novo recurrent Xp11.23p11.22 microduplication in eight patients (two males and six females) from a large cohort of patients presenting with syndromic intellectual disability. This 4.5 Mb microduplication is mediated by nonallelic homologous recombination between D-REP and P-REP segmental duplications. This duplicated region contains many genes such as PQBP1, FTSJ1, SYP and SHROOM4 responsible for intellectual disability and BMP15 involved in ovarian dysgenesis.
So far, fourteen females and five males with this microduplication have been reported in the literature. Associated clinical manifestations include language impairment, mostly severe, moderate to severe intellectual disability and abnormal electroencephalogram. Other features such as epilepsy, overweight and early puberty have also been reported. Here, we report on seventeen new patients (nine females and eight males) presenting with an Xp11.23p11.22 microduplication detected by array CGH. The 4.5 Mb recurrent duplication was identified in five patients whereas twelve patients harbor an atypical duplication with various breakpoints. These new patients offer the opportunity to better define the phenotype associated with this microduplication and to identify minimal critical regions highlighting some possible candidate gene(s) for specific clinical feature(s).

Mosaic Variegated Aneuploidy syndrome: a new case of *CEP57* mutation in a 4-years-old girl and review of the literature.

L. Pinson[1], *L. Mannini*[2], *M. Willems*[1], *G. Lefort*[3], *A. Schneider*[3], *P. Blanchet*[1], *C. Coubes*[1], *E. Haquet*[1], *D. Geneviève*[1], *P. Sarda*[1,3], *J. Puechberty*[1,3], *F. Cucco*[2,4], *A. Musio*[2,5];
[1]*Département de Génétique Médicale, Hôpital Arnaud de Villeneuve, Montpellier, France,* [2]*Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Pisa, Italy,* [3]*Laboratoire de Génétique Chromosomique, Hôpital Arnaud de Villeneuve, Montpellier, France,* [4]*Dipartimento di Biologia, Università di Pisa, Pisa, Italy,* [5]*Istitiuto Toscano Tumori, Florence, Italy.*

Mosaic Variegated Aneuploidy (MVA) syndrome is a rare autosomal recessive disorder characterized by constitutional aneuploidy and predisposition to cancer. Typically, individuals with MVA display growth retardation, facial dysmorphism, variable congenital defects and developmental delay. MVA is a heterogenetic condition caused by mutations in *BUB1B* and *CEP57* genes, both involved in mitotic spindle and microtubule stabilization.
We report a 4-year-old girl, second child of first cousin parents, presenting with pre and post natal growth retardation, dysmorphic features including mild rhizomelic shortening of the upper limbs and mild mental delay. During follow-up, the proband does not show tumor development.
Diagnosis of MVA syndrome was suspected based on cytogenetic data. Molecular investigations identified a homozygous 11 base pair insertion in *CEP57* gene. This insertion, reported in three of the four previously *CEP57* mutation-positive individuals, is the most common causal *CEP57* mutation in MVA syndrome.
When compared to the literature, our report confirms certain clinical features in *CEP57* mutated MVA cases, such as growth retardation with relative sparing of the head and normal or mildly delayed development. Rhizomelic shortening of uppers limbs has already been observed in two other *CEP57* mutation carriers and may be a specific feature.
In contrast with the *BUB1B* mutated probands, so far no cancer has been reported in *CEP57* mutation-positive individuals.
Since few cases of patients with MVA syndrome caused by *CEP57* mutations have been reported, the careful description of further cases is important to better delineate the phenotypic spectrum and confirm phenotype genotype-correlation.

P02.099

Lines of Blaschko as a manifestation of (functional) mosaicism in 4 female cases with different disorders

J. van den Ende[1,2], *N. Van der Aa*[1,2], *B. Loeys*[1,2];
[1]*Department of Medical Genetics, University Hospital Antwerp, Edegem (Antwerp), Belgium,* [2]*University of Antwerp, Antwerp, Belgium.*

Patterned pigmentary disturbances are seen in a large variety of human genetic disorders. Cytogenetic studies have provided evidence that such skin lesions often reflect chromosomal mosaicism.
In women X-inactivation results in functional mosaicism, and in X-linked skin disorders this can manifest itself by the appearance of pigmented skin striations following Blaschko`s lines. This has been reported for several X-linked diseases, like Incontinentia Pigmenti, caused by mutations in the NEMO gene, Focal Dermal Hypoplasia, caused by PORCN mutations, Christ-Siemens-Touraine syndrome etc. In these conditions heterozygous females often show a Blaschko-linear pattern of Lyonization.
With techniques like SNP array copy number variations can be detected containing genes on the X-chromosome, that lead to severe diseases in males, but in females can lead to the typical skin changes.
Also mosaics of other (cryptic) chromosome abnormalities can lead to the same skin lesions.
We show four female patients with streaky hyperpigmentation following the lines of Blaschko, with or without accompanying symptoms; one with a de novo deletion on Xq26.2-26.3, containing the PHF6 gene, responsible for the Borjeson-Forssman-Lehmann syndrome in males, and the HPRT1 gene, responsible for the Lesch-Nyhan syndrome in males. The second patient shows a hypomorphic mutation in the NEMO gene, giving rise to Hypohydrotic Ectodermal Dysplasia with Immune-deficiency in males. The third patient is a girl with a mosaic trisomy 14, and in the fourth patient a mosaic maternal isodisomy 11q13.4-qter was found by SNP array analysis.

Mowat-Wilson syndrome (MWS) is an intellectual disability (ID) - distinctive facial gestalt -multiple congenital anomaly syndrome, with features of microcephaly, epilepsy, corpus callosum agenesis, conotruncal heart defects, urogenital malformations and Hirschsprung disease (HSRC). MWS is caused by de novo heterozygous mutations in the ZEB2 gene. The majority of mutations lead to haplo-insufficiency through premature stop codons or large gene deletions. Only three missense mutations have been reported so far, none of which resides in a known functional domain of ZEB2 protein.
In this study, we report and analyze the functional consequences of the first missense mutations, p.Tyr1055Cys, p.Ser1071Pro, and p.His1045Arg, identified in the highly conserved C-zinc finger (C-ZF) domain of ZEB2, in three unrelated patients. Their phenotypes included a facial gestalt reminiscent of MWS and moderate ID, but no microcephaly, heart defects, or HSRC. In-vitro studies showed that all three mutations prevented binding and repression of the E-cadherin promoter, the best-characterized ZEB2 target gene. Taking advantage of zebrafish morphant technology, we performed rescue experiments using wild-type and mutant human ZEB2 mRNAs. Variable, mutation-dependent, embryo rescue, correlating with the severity of patients' phenotype, was observed.
Our data provide evidence that these missense mutations cause a partial loss of function, suggesting that ZEB2 role is not restricted to repression of E-cadherin. Functional domains other than C-ZF may play a role in early embryonic development. Finally, these findings broaden the clinical spectrum of ZEB2-mutations, indicating that MWS ought to be considered in patients with moderate ID, suggestive facial gestalt, and no congenital malformation.

P02.101

New case supporting the evidence that LAPS and Myhre syndromes are clinical variants of the same disorder caused by mutations in *SMAD4*

A. Topa[1], *F. Sewon*[2], *A. Fasth*[3,4];
[1]*Department of Clinical Genetics, Sahlgrenska University Hospital, Gothenburg, Sweden,* [2]*Department of Paediatrics, Gävleborg Regional Hospital, Gävle, Sweden,* [3]*Department of Paediatric Immunology, Queen Silvia Children's Hospital, Gothenburg, Sweden,* [4]*University of Gothenburg, Gothenburg, Sweden.*

We report the case of a boy of Scandinavian descent diagnosed with Myhre syndrome (MS) at the age of ten years. The patient was initially diagnosed with CHARGE syndrome based on the association of unilateral choanal atresia, patent ductus arteriosus, soft cleft palate with swallowing difficulties necessitating PEG, growth retardation, cryptorchidism, bilateral hearing loss and immunoglobulin deficiency explaining his recurrent bacterial respiratory tract infections. The absence of iris- and/or retinal coloboma, normal semicircular canals and no typical dysmorphic features, however, made CHARGE a less likely diagnosis. Furthermore, the patient has progressive restrictive pulmonary disease, not explained by his immunodeficiency, as well as delayed wound healing and chronic pericarditis requiring permanent immune suppression. MS was suspected based on the presence of typical dysmorphic features, short stature, hearing impairment and limited joint mobility. A heterozygous mutation in *SMAD4* affecting the codon for Ile500 (c.1498A>G, p.Ile500Val) confirmed the diagnosis. He also has signs of precocious puberty with so far no evidence of hormonal imbalance. This is in line with a previous report suggesting hypothalamic-hypophyseal malfunction in MS [Asakura et al., 2012]. The presence of respiratory problems and chronic pericarditis supports a previously reported observation that LAPS syndrome (**L**aryngotracheal stenosis, **A**rthropathy, **P**rognathism, and **S**hort stature) and MS are in fact phenotypic variants of the same disorder [Lindor et al., 2012]. This case is particular by the finding of immunoglobulin deficiency, chronic immune pericarditis and delayed wound healing indicating a role for the SMAD4 and TGF Beta Signaling in immune and inflammatory response.

P02.102

A new autosomal recessive disorder with hydrops fetalis, arthrogryposis multiplex congenita, neuronal migration disorder, adrenal and pulmonary hypoplasia and renal abnormalities

T. Uster[1], *P. Shannon*[1], *J. Michaud*[2], *D. Chitayat*[1,3];
[1]*Mount Sinai Hospital, Toronto, ON, Canada,* [2]*St-Justine Hospital Research Centre, Montreal, QC, Canada,* [3]*Hospital for Sick Children, Toronto, ON, Canada.*

Objectives: We report male and a female siblings, born to a consanguineous Turkish couple, with hydrops fetalis (HF), neuronal migration disorder, joint contractures, pulmonary and adrenal hypoplasia and renal abnormalities. To our best knowledge this is a hitherto new, autosomal recessive condition.

The parents were healthy and first cousins of Turkish descent. Patient A, a male, was born at 31.8 weeks gestation following a pregnancy complicated with HF, mild ventriculomegaly, misalignment of the skull bones and lumbar lordosis. He died shortly after delivery and autopsy showed HF, cleft palate, ambiguous genitalia, bilateral talipes equinovarus, camptodactyly of the fingers and clenched fists. There was a butterfly T5 vertebra and hypoplastic lungs, kidneys and adrenal glands. The brain showed megalencephaly, abnormal gyration and an unusual pattern of cytoarchitextural disturbance in the cerebral cortex. The karyotype was 46, XY.

Patient B, a female, the product of the couple's second pregnancy, was found to have an increased nuchal translucency and body edema on ultrasound at 12 weeks gestation. Ultrasound at 20 weeks gestation showed bilateral talipes equinovarus, flexed wrists, echogenic kidneys, pericardial effusion and an abnormal cerebral configuration. The pregnancy was terminated at 21 weeks gestation and the autopsy showed the same findings as in her late brother apart from her female internal and external genitalia. Microarray analysis was normal and female. Extensive investigations done on both siblings failed to identify an eatiology. The couple subsequently had three unaffected pregnancies. Investigations are currently ongoing to identify the causative gene.

Nicolaides-Baraitser syndrome due to a large intragenic SMARCA2 deletion

V. Y. Voinova[1,2,3], *S. G. Vorsanova*[1,2,3], *Y. B. Yurov*[1,2,3], *I. Y. Iourov*[3,1];
[1]*Institute of Paediatrics and Children Surgery, Ministry of Health, Moscow, Russian Federation,* [2]*Moscow State University of Psychology and Education, Moscow, Russian Federation,* [3]*Mental Health Research Center, Russian Academy of Medical Sciences, Moscow, Russian Federation.*

Nicolaides-Baraitser syndrome (NBS) is usually caused by SMARCA2 mutations and is characterized by short stature, hypotrichosis, mental retardation and typical facial appearance. We report a case of NBS due to an intragenic SMARCA2 deletion detected by oligonucleotide SNP array CGH. A 24-month-old girl is the only child of healthy parents born from the second pregnancy at 37 weeks with low birth weight. She had poor appetite and low weight gain. Her parents have noted hair loss, short stature and development delay. Physical examination showed low height (3d percentile) and weight (<3rd percentile) and small head circumference (<3rd percentile). The child had pectus excavatum, umbilical and bilateral inguinal hernia. She presented with sparse and thin (vellus) hair over the scalp with normal eyebrows/eyelashes, partial alopecia (occipital region), triangular face, downslanting palpebral fissures, broad nasal tip with anteverted alae nasi, thin upper and thick prominent lower lip, broad and long philtrum, wide mouth, large protruding tongue. The patient had diffuse muscle hypotonia. She was sociable, good-natured and smiling. Seizures, speech delay, enlarged kidneys with a thickened renal parenchyma and incomplete myelination were observed. High-resolution (~1kb) oligonucleotide SNP array (CGH) analysis has shown the presence of a deletion within 9p24.3. The size of the deletion was estimated as 88 kb spanning 21 exons of SMARCA2. To date, this is the first NBS case associated with such a large intragenic SMARCA2 deletion. The index case shows that high-resolution oligonucleotide SNP array analysis is able to detect intragenic deletions causing extremely rare monogenic conditions.

Nijmegen Breakage Syndrome: a possibilities of postnatal and prenatal diagnostics in Belarus

N. Rumiantsava[1], *I. Naumchic*[1], *S. Sharapova*[2], *T. Egorova*[1], *K. Mosse*[1], *A. Polityko*[1], *V. Kulak*[1], *R. Chmel*[1], *O. Zobikova*[1], *S. Golubeva*[1];
[1]*Republican Medical Centre "Mother and Child", Minsk, Belarus,* [2]*Belarusian Research Center for Pediatric Oncology, Hematology and Immunology, Minsk, Belarus.*

"Nijmegen Breakage Syndrome" (NBS, MIM 251260) is autosomal recessive disorder with distinct phenotype. Patients selected for moleqular testing based for well-known criteria: microcephaly, mental, growth delay, typical facial features, immunodeficiency, chromosome instability (CIN). We present the scheme of NBS diagnostics used in Belarus. Results. Patients (4 sporadic cases, 2 sibs) were born at term. Variations of birth weight were 2300-3330g; length 48-52cm; OFC 28-31cm. Age of diagnosis detection was: at infancy (1), first year (3), during 3-6 years (2). All showed severe microcephaly, characteristic facial appearance, growth, mental retardation, anemia, sinopulmonary infections, humoral/cellular immunodeficiency, normal karyotype. One had polydactyly. Frequency of chromosomal rearrangements was 13-23%; typical aberrations presented were inv(7); t(7;14); t(14;14); del(14); dic(7;7). DNA testing revealed mutations in exon 6 NBS gene: c.657_661del5 (2 sporadic cases); c.764-768delAAAAC (familial case). All patients were homozygous. Prenatal DNA study was performed in one family: fetus was heterozygous for mutant allele c.657_661del5. Familial case. Proband - fetus (G2) with ventricular erlangement, microcephaly detected by sonography during 1-2st trimesters (karyotype 46,XX). Parents refused from pregnancy termination. Newborn presented low weight, microcephaly. Elder child (6 years old), firstly counseled at same time, showed microcephaly, dysmorphisms, growth and mental delay, recurrent infections, CIN. We have established NBS based on characteristic pattern of clinical, cytogenetical, immunological data, confirmed by mutation analysis. Patients care: follow-up to monitor mentality, growth, immunological status, malignancy. Diagnostics. Genetic counseling of affected children with normal karyotype>NBS suspected>CIN investigation>Test positive>DNA investigation>NBS confirmation>Genetic prognoses>Prenatal NBS diagnostics in families with known mutations.

Identification of two novel mutations in the *NOG* gene in patients with Symphalangism syndrome

A. Ganaha[1], *T. KANAME*[2];
[1]*Department of Otorhinolaryngology-Head and Neck Surgery, Nishihara Okinawa, Japan,* [2]*Department of Medical Genetics, University of the Ryukyus, Okinawa, Japan, Nishihara Okinawa, Japan.*

Background

NOG maps to human chromosome 17q22, which encodes a protein named noggin that is essential to bone and joint development. The NOG gene mutations, which lead to aberrant functions of the noggin protein, give rise to different digit anomaly syndromes. One of these syndromes is a syndrome with autosomal dominant proximal symphalangism and congenital conductive hearing impairment. We investigated the NOG gene in 3 patients from 3 unrelated families, who were clinically diagnosed with proximal symphalangism and conductive hearing loss.

Result

All patients had bilateral conductive hearing loss and symphalangism. Exploratory tympanotomy was done in two patients. Stapes ankylosis was identified in both patients. Hyperopia was identified in two out of three patients. Syndactyly was identified in one patient.

Mutation analysis of the NOG gene was performed in all patients. Missense mutations of the NOG gene were identified in two out of three patients. The mutations were causing p.P187A and p.C228S, respectively. We could not find any pathological mutations of NOG gene in one patient.

Conclusion

We identified two novel mutations causing p.P187A and p.C228S in patients with symphalangism spectrum disorder. The NOG gene mutations give rise to a various spectrum of clinical findings. These two novel mutations and clinical manifestations in patients will contribute to understanding genotype/phenotype correlation of the NOG mutations.

Multiple hemangiomatosis in a child with Noonan syndrome due to a SHOC2 mutation

C. Colson[1], *M. Decamp*[1], *A. Molin*[1], *C. Mignot*[2], *H. Cavé*[3], *M. Kottler*[1], *G. Plessis*[1], *A. Dompmartin*[4], *M. Gérard*[1];
[1]*Service de Génétique, Caen, France,* [2]*Service de Neuropédiatrie, Hôpital Trousseau, Paris, France,* [3]*Biologie Moléculaire, Hôpital Robert Debré, Paris, France,* [4]*Service de Dermatologie, Caen, France.*

Noonan syndrome (NS) and RASopathies are recognizable on clinical history and characteristic dysmorphologic features, with usual skin expression. Classical skin features are deep plantar and palmar creases, icthyosis, eczema, keratosis pilaris, cafe-au-lait spots, and lentigines. Skin vascular abnormalities are not commonly described. We report an atypical case of NS with multifocal hemangiomatosis and a SHOC2 mutation. The girl is the first born of non-consanguineous parents without family history of vascular anomalies. The pregnancy was marked by enlarged nuchal translucency. At birth, macrosomia and disseminated small infantile hemangiomas was noted, with more than 50 millimetric angiomas. No hepatic or brain angiomas were found by US and MRI. Clinical examination of the girl showed widely spaced nipples, short neck and posteriorly rotated ears. Sequential gene exploration of RASopathies found a mutation in SHOC2 gene. SHOC2 is associated with the phenotype of Noonan syndrome with loose anlagen hair. Multifocal hemangiomatosis is not associated at our knowledge in Noonan syndrome or other rasopathies, but PTPN11 (SHP-2) has been shown to regulate vascular signalling and angiogenic events in MAP Kinase pathway (Mannell and Krötz, 2012). Vascular malformations have already been described in Noonan's syndrome : multiple pulmonary arteriovenous fistulas, moya-moya, aneurysms and aortic dilatation, additionally to the known cardiac malformations. Vascular tumors, such as hemangiomatosis, especially diffuse, may be another part of RASopathies spectrum.

P02.107

Prevalence and frequency monogenetic syndromes of multiple congenital malformations in population of Rostov region (Russia)

T. Ponomareva[1], *S. Amelina*[2], *R. Zinchenko*[3];
[1]*Scientific Research Institute of Biology, Rostov-on-Don, Russian Federation,* [2]*Scientific Research Institute of Biology „Southern Federal University", Rostov-on-Don, Russian Federation,* [3]*Research Centre for Medical Genetics, Russian Academy of Medical Sciences, Moscow, Russian Federation.*

A medical genetically study of the population of the Rostov region was carried out (12 districts - 497,460 total surveyed persons, 97,345 surveyed children (aged 0 to 18 years)). Information on births in the studied 12 districts of the Rostov region allocated for the period 2000-2011, of the accounting monitoring of congenital malformations (CM) (born alive and stillborn 64,215 people). Monogenic syndromes of multiple congenital malformations (MSMCM) was examined. The overall prevalence of MSMCM was 1:2211 persons. The proportion of children was 58%, the share of adult age was 42%. As the severity of the CM is variable, children with this condition may not survive to adulthood. Therefore, a more reliable assessment of the prevalence of MSMCM for the child population. The overall prevalence of MSMCM was 1:716 children. Among the syndromes MSMCM with autosomal dominant (AD) inheritance type was identified 29 diseases in 85 children, with autosomal recessive (AR) inheritance type - 17 diseases in 44 children, with X-linked type of inheritance - 4 of diseases in 7 children. Among patients with MSMCM with AR inheritance type children are predominat (72%). Population frequency of MSMCM was 160:100,000. Population frequency were revealed for some MSMCM: Noonan syndrome (frequency of 9:100,000), hemifacial microsomia (8:100,000), constricting bands, congenital (8:100,000), DiGeorge syndrome (8:100,000), Tel Hashomer camptodactyly syndrome (6:100,000), Coffin-Siris syndrome (6:100,000), Waardenburg syndrome, type I (5:100,000), Holt-Oram syndrome (5:100,000), Dubowitz syndrome (5:100,000), Cousin syndrome (5:100,000), Seckel syndrome (5:100,000), CHARGE syndrome (5:100,000), VATER-association (5:100,000). These results agree with data previously surveyed populations of Russia.

P02.108

Further expanding both the genotype and phenotype associated with germline NRAS mutation

J. Gillis, *S. MacKay, A. Crowley;*
IWK Health Centre/Dalhousie University, Halifax, NS, Canada.

We present a case of a female infant who presented small for gestational age with multiple abnormalities including; polyhydramnios, intracerebral arachnoid cyst, bilateral cystic hygroma and hydronephrosis on prenatal ultrasound. She had a normal karyotype on amniocentesis. Mother declined prenatal genetic testing for Noonan syndrome. On follow up after birth she was notably dysmorphic with wide sutures, reddish blonde and sparse hair which was abnormal in texture. She struggled with hypoglycemia and developed apneic spells and episodes of seizure. She was hypotonic, did not feed well and required NG tube placement. Further investigations revealed duplication of the collecting system with moderate hydronephrosis, ureteroceles and small cortical cysts bilaterally. Brain imaging was abnormal and echocardiogram identified an ASD and bicommissural aortic valve. She failed her newborn hearing screen and suffers from numerous urinary tract and skin infections. Her milestones are delayed and she has ongoing GI issues. Molecular genetic testing for Noonan syndrome identified a previously uncharacterized germline mutation in the neuroblastoma RAS viral (v-ras) oncogene (NRAS). Previously thought to be restricted to somatic mutations, three novel germline NRAS mutations have recently been reported in nine patients presenting with features suggestive of the Noonan syndrome spectrum. Although our patient shares many of the previously reported characteristic features, our patient is the tenth world wide to be reported, harbors yet another novel de novo NRAS mutation and demonstrates a more severe phenotype which was evident prenatally.

Molecular spectrum in a group of Spanish and German patients with RASopathies

V. López-González[1], *M. J. Ballesta-Martínez*[1], *G. Glover-López*[2], *R. Moya-Quiles*[2], *B. Ezquieta-Zubicaray*[3], *F. Lepri*[4], *J. C. Czeschik*[5], *A. Küchler*[5], *B. Albrecht*[5], *D. Wieczorek*[5], *M. Zenker*[6], *E. Guillén-Navarro*[1];
[1]*Unidad de Genética Médica. Servicio de Pediatría. Hospital Clínico Universitario Virgen de la Arrixaca, Murcia, Spain,* [2]*Centro de Bioquímica y Genética Clínica. Hospital Clínico Universitario Virgen de la Arrixaca, Murcia, Spain,* [3]*Laboratorio de Diagnóstico Molecular. Hospital General Universitario Gregorio Marañón, Madrid, Spain,* [4]*Bambino Gesù Pediatric Hospital, IRCCS, Rome, Italy,* [5]*Institut für Humagenetik, Universtitätsklinikum Essen, Essen, Germany,* [6]*Institute of Human Genetics, University Hospital of Magdeburg, Magdeburg, Germany.*

INTRODUCTION: RASopathies, including Noonan (NS), Cardiofaciocutaneous (CFCS), Costello (CS), LEOPARD (LS), Legius syndromes and Neurofibromatosis type I (NF1), are due to mutations in twelve different genes of the RAS/MAPK pathway. Our aim is to know the genotype in a RASopathy group of patients.
MATERIAL AND METHODS: We reviewed the charts of 67 patients with RASopathy (36 from Spain and 21 from Germany) and analyzed its molecular basis.
RESULTS: 35 males and 32 females. Median age at referral: 1.5 years. Positive family history: 13 (19.4%). Phenotype: NS 52 (77.6%), CFCS 9 (13.4%), LS 2 (3%), CS 2 (3%), and Legius syndrome 2 (3%). In 57 patients (85 %) a pathogenic mutation was identified. In 10 PTPN11 mutation negative patients (9 NS / 1 CFC) molecular analysis is ongoing (15%). Mutations were indentified in 43/52 NS (82.7%): 36 PTPN11 (83.7%), 4 NF1 (9.3%), 2 SOS1 (4.6%) and 1 SHOC2 (2.3%); 8/9 CFCS (89%): 4 BRAF (50%), 2 KRAS (25%), 1 MEK1 (12.5%) and 1 RAF1 (12.5%). Y279C PTPN11 mutation was in both LS, HRAS in 2 CS and SPRED1 in 2 Legius syndrome. Higher proportion of PTPN11 mutations was in exon 3, 8 and 13 (34.3%, 28.6% and 22.9% respectively).
CONCLUSION: Compare to previous reports, we find higher PTPN11 mutation detection rate (83.7% vs 50%), maybe due to stringent criteria, and similar molecular CFCS data and PTPN11 hotspots. The lower rate of SOS1 mutations might be associated to the previous lack of access to the study of other RAS/MAPK genes.
This work has been supported in part by a grant from the DAAD (Deutscher Akademischer Austausch Dienst - German Academic Exchange Service) and „Fondo de Investigaciones Sanitarias (PI 06/1179)".

P02.110

Novel substitutions in patients with a RASopathy phenotype: pathogenic mutations or benign polymorphisms?

M. Pelc[1], *E. Ciara*[1], *S. Łuczak*[1], *M. Kugaudo*[1,2], *M. Jędrzejowska*[1,3], *A. Cieślikowska*[1], *A. Jakubiuk-Tomaszuk*[4], *J. Trubicka*[1], *D. Piekutowska-Abramczuk*[1], *D. Jurkiewicz*[1], *P. Kowalski*[1], *M. Borucka-Mankiewicz*[1], *K. Chrzanowska*[1], *M. Krajewska-Walasek*[1];
[1]*Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland,* [2]*Department of Child and Adolescent Psychiatry, The Medical University of Warsaw, Warsaw, Poland,* [3]*Neuromuscular Unit, Mossakowski Medical Research Centre, Polish Academy of Sciences, Warsaw, Poland,* [4]*Department of Pediatric Laboratory Diagnostics, Medical University of Bialystok, Bialystok, Poland.*

The RASopathies are a group of congenital syndromes with multiple anomalies, including dysmorphic craniofacial features, cardiac, skin and musculoskeletal defects and developmental delay. The RASopathy disorders involve such syndromes as: Noonan (NS), Cardiofaciocutaneous (CFCS), LEOPARD (LS) and other. They result from germline mutations in genes encoding components of the Ras/MAPK signaling cascade. We present a group of eight unrelated patients with novel substitutions in different Ras/MAPK genes, causative of NS, LS or CFCS phenotype. The identified variants were heterozygous missense substitutions: c.166A>G in *PTPN11*, c.784A>T, c.1913C>T in *RAF1*, c.2165G>A, c.2371C>A in *SOS1* and c.785A>C, c.1502A>C, c.1783T>C in *BRAF*. All were absent in the control alleles. To predict whether the novel variant is tolerated or deleterious, we used the combined results of four computer algorithms: SIFT, PMut, PolyPhen-2 and Mutation Taster, which confirmed pathogenicity of all *BRAF* mutations and one *RAF1* substitution (c.784A>T), in accordance to observed CFCS and LS symptoms, respectively. The two *SOS1* substitutions, found in two patients and their parents, were recognized recently as SNPs of unknown clinical consequence. The results for the remaining two variants (c.166A>G and c.1913C>T) were ambiguous, mostly suggesting them as possibly benign. Nonetheless, the detailed clinical manifestations of all patients suggest a Ras/MAPK pathway defect. We presume that introduction of novel mutations in the Ras/MAPK genes might contribute to defining possible differences in the features presented by the patients and enable more precise phenotype-genotype correlations in the RASopathies. The research was supported by NCN Project UMO-2011/03/N/NZ2/00516 and EU Structural Funds Project POIG.02.01.00-14-059/09.

Otopalatodigital syndrome type 1 (OPD1), and 2 (OPD2), Melnick-Needles syndrome (MNS), and frontometaphyseal dysplasia (FMD), belong to OPD syndrome spectrum disorders, caused by mutations in the *FLNA* gene. Overlapping phenotypes are described. Males are more severely affected than females, up to perinatal death of affected males with MNS. We report the first series of 9 fetuses (1 female and 8 males) sent to our laboratory for *FLNA* analysis with a phenotype belonging to the OPD spectrum.
We studied the whole coding sequence of *FLNA* by using either dHPLC or HRM and PCR-sequencing on both strands. A missense mutation was identified in 3 male fetuses: the MNS recurrent mutation p.Ser1199Leu and 2 novel variants in exons 4 and 34. A synonymous variant was identified in 2 brothers but RNA studies did not show any splicing effect.
In our series, the mutation rate is lower than that of postnatal series. The diagnosis is probably more difficult to refine clinically given the absence of certain diagnostic criteria. Hypertelorism, cleft palate, abnormal hands and feet, heart defects and brain anomalies are relevant criteria for fetal OPD2 diagnosis. Radiological signs are more difficult to identify. For the MNS, abnormality of the anterior segment of the eye seems to be a good criterion for the diagnostic orientation. Cleft palate may also be seen, although not originally described in this syndrome. The diagnosis of OPD spectrum disorders is important in fœtopathology because it will provide affected families to appropriate genetic counseling for future pregnancies.

Further Delineation of the Johnston-Biesecker Multiple congenital anomalies-hypotonia-seizures syndrome caused by a single PIGA mutation

K. Steindl[1], *P. Joset*[1], *D. Bartholdi*[1], *S. Pajarola*[1], *S. Böhm*[2], *J. Micallef*[2], *A. Rauch*[1];
[1]*Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland,* [2]*Eastern Swiss Pediatric Hospital, St. Gallen, Switzerland.*

Somatic mutations in the X-linked PIGA gene [MIM 311770] encoding phosphatidylinositol glycan class A are known to cause paroxysmal nocturnal hemoglobinuria, while germline mutations were assumed embryonic lethal. Johnston and colleagues only recently described a PIGA nonsense mutation p.Arg412* with residual function in a family segregating with an X-linked lethal disorder involving cleft palate, neonatal seizures, contractures, central nervous system structural malformations and other anomalies (Johnston et al. Am J Hum Genet 2012). While
three boys of this family were affected, two carrier females with 100% skewing of X-inactivation were healthy. We now identified the same p.Arg412* mutation in an unrelated boy by whole exome sequencing.
Like the previous cases this boy was born with macrosomia, short neck, facial dysmorphism and cerebral anomalies such as hypoplastic cerebellum and immature white-matter. The neonatal course was complicated by absence of spontaneous movements, respiratory insufficiency and intractable myoclonic-tonic seizures. The boy developed sepsis from necrotizing enterocolitis and deceased at the age of 15 days.
In addition to the reported features this boy showed hepatosplenomegaly and remarkable short tubular bones verified by X-ray measurements to approximately correspond to the 3rd centile. The healthy carrier mother showed only mild skewing of X-inactivation in blood (83:17). The family history was remarkable for one male stillbirth of the sister of the maternal grandmother. We therefore confirm that boys with the PIGA p.Arg412* mutation show a distinct pattern of morphological anomalies and are prenatally viable, but die soon after birth due to respiratory failure and intractable seizures.

A clinical and molecular study of Pitt-Hopkins syndrome in Japan

N. Okamoto, *Y. Yamamoto, K. Ohmachi;*
Department of Medical Genetics, Osaka Medical Center for Maternal and Child Health, Osaka, Japan.

Pitt-Hopkins syndrome (PTHS) is characterized by severe motor and mental retardation, a characteristic facial features and episodic hyperventilation. Language development is almost absent. Characteristic facial features include a coarse face, a broad nasal bridge and a wide mouth with prominent Cupid's bow. Researchers revealed that microdeletion of chromosome 18q21.1 including *TCF4* in patients with PTHS. De novo missense mutations in *TCF4* gene were identified. *TCF4* is a class I basic helix-loop-helix transcription-factor and involved in neuronal development. Pitt-Hopkins-like syndrome-1 is caused by mutation in the *CNTNAP2* gene on chromosome 7q35, and Pitt-Hopkins-like syndrome-2 is caused by mutation in the *NRXN1* gene on chromosome 2p16.3.
The number of the patients with PTHS increased. So far, reports of Japanese patients with PTHS were few. We studied Japanese patients with PTHS and found 10 novel mutations. Most of them have been diagnosed as atypical Rett syndrome or Angelman syndrome. We studied patients by direct sequencing of coding regions and MLPA analysis for deletions. Most of the mutations generated premature stop codons. Some missense mutations were localized in the highly conserved amino acid in the bHLH domain. All patients showed typical features of PTHS and had severe intellectual disability. Incidence of breathing abnormality and epileptic seizures were low among our patients. However, some typical patients did not have *TCF4* mutations. Further genetic analysis including next generation sequencing is proceeding.

Poland Anomaly (PA) is a congenital disorder presenting with agenesis/hypoplasia of the pectoralis major muscle variably associated with thoracic and/or upper limb anomalies, incidence 1/30000 births, higher prevalence in males. Most cases are sporadic, but familial recurrence, with different inheritance patterns, has been observed. The PA genetic etiology remains unknown. Since PA involved structures may originate from the same embryonic tissues, genes controlling cell proliferation, migration, and differentiation of these tissues might be involved. Alternatively, one common assumption is that PA may origin from an embryonic vascular insult indicating genes controlling vessels development as indirectly involved.
We recruited a large cohort of PA patients (more than 200, about 10% familial) classified into homogeneous subgroups based on their phenotype features. Karyotype analysis performed in 128 patients has not shown any relevant alterations. The arrayCGH revealed the presence of chromosome anomalies in 19 out of 119 analyzed patients: 10 genomic duplications, some of which overlap common copy number variant (CNV) regions, and 9 heterozygous deletions in different regions outside evident CNVs.
Bioinformatic analysis of arrayCGH data indicates gene enrichment in different pathways including those involved in cell-cell adhesion and muscle structure development.
The screening of these genes in our cohort of patients will contribute to confirm their roles in PA. Although clinical and genetic heterogeneity make the task difficult, the use of next generation sequencing (NGS), the availability of a large cohort of patients and familial cases with dominant inheritance and full penetrance, will be helpful to identify PA causative genes.

Polydactyly is a common skeletal feature in ciliopathies and recognized as a hallmark diagnostic feature such as for example in Bardet-Bield syndrome (BBS). Polydactyly is mainly postaxial in ciliopathies, except in syndromes related to the GLI3 pathway (such as Greig, acrocallosal and hydrolethalus syndromes) for which lower limb polydactyly is preaxial whereas postaxial for the upper limb. This presentation has also been reported for Oro-Facial-Digital (OFD) syndromes in particular type IV, with *TCTN3* mutations known to impact the transduction of SHH signaling. Moreover, mesoaxial polydactyly has been reported mainly in other ciliopathies: Pallister-Hall syndrome with mutations in *GLI3* and several types of OFD syndromes in particular type VI (unknown genetic basis to date).
In our cohort of patients presenting with BBS and carrying mutations in *BBS1* to *BBS16* genes, 89% had at least one extra digit that was always postaxial.
Recently, we reported on a BBS family mutated in *LZTFL1* (*BBS17*) presenting with mesoaxial polydactyly as an outstanding manifestation (Marion et al., 2012). Herein, we report on twin sisters presenting with classical BBS and mesoaxial polydactyly. They are compound heterozygotes for novel *LZTFL1* mutations confirming this clinical finding as highly suggestive for *BBS17*.
LZTFL1 was identified as an important negative regulator of the BBSome ciliary trafficking and SHH pathway signaling. The association of mesoaxial polydactyly and mutations in *LZTFL1* confirms the impact of SHH pathway in the development of the limbs and patterning of the digits.

Clinical features in patients with *PTEN* germline mutation diagnosed in childhood, except familial Cowden syndrome and Autism Spectrum Disorder.

T. BUSA[1], *B. CHABROL*[1], *M. MILH*[1], *N. DEGARDIN*[1], *M. LONGY*[2], *S. SIGAUDY*[1], *N. PHILIP*[1];
[1]*Hopital de la Timone Enfants, Marseille, France,* [2]*Institut Bergonié, Bordeaux, France.*

PTEN gene (MIM 601628) is implicated in *PTEN* hamartoma tumor syndromes (PHTS) including Cowden syndrome (CS) and Bannayan-Riley-Ruvalcaba syndrome (BBRS). BBRS, considered as the childhood form, is characterized by macrocephaly, intestinal hamartomatous polyposis, lipomas and pigmentation macules of the penis. Half of the patients have also mild to severe mental retardation. Recently, children with macrocephaly and autism spectrum disorders (ASD) without other symptoms of PHTS have been reported.
We report 6 children carrying a *PTEN* mutation, in the absence of ASD or family history of CS, who were diagnosed from 1 January 2009 to 31 December 2012. The raison of referral was lipoma (1/6), isolated macrocephaly (1/6), developmental delay (3/6) and severe facial arteriovenous malformation (1/6). Only three patients partially met the clinical diagnosis of BBRS. All patients had macrocephaly at the time of diagnosis (average at +6.5DS). Three patients had also overgrowth without advanced bone age. Four patients had cerebral MRI that showed enlarged cerebral ventricles or prominent subarachnoid spaces (4/4), abnormal periventricular white matter (2/4), abnormal cortical pattern (2/4) and thick corpus callosum (1/4). Concerning the mutations, 2 patients carried a nonsens mutation, 4 patients a missense mutation. The mutation occurred de novo in 3 patients. The two others related patients had a familial history of macrocephaly and mild developmental delay without cancer history.
This report emphasizes the variability of phenotype associated with *PTEN* mutation in children. Only half of the patients presented several criteria of BBRS. Macrocephaly was the most constant manifestation. Cerebral MRI showed nonspecific anomalies.

Intra- and inter-familiar variability in Saethre-Chotzen syndrome

A. Beleza[1], *L. Ramos*[1], *F. Ramos*[1,2], *J. Sá*[1,3], *S. B. Sousa*[1,4], *M. Venâncio*[1,2], *J. Saraiva*[1,2];
[1]*Clinical Genetics Department - Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal,* [2]*Faculty of Medicine, University of Coimbra, Portugal, Coimbra, Portugal,* [3]*CGC Genetics- Centro de Genética Clínica, Porto, Portugal,* [4]*Institute of Child Health, University College London, London, United Kingdom.*

Background: Saethre-Chotzen syndrome (SCS) is a rare syndromic craniosynostosis, commonly involving the coronal suture and usually associated with facial craniofacial dysmorphism and digit abnormalities. Hearing loss, ophthalmologic complications and increased intracranial pressure may occur. SCS is caused by loss-of-function mutations in *TWIST1* and is inherited in an autosomal dominant manner. Many individuals diagnosed with SCS have an affected parent.
Methods: A retrospective analysis was performed on all patients with a confirmed *TWIST1* gene abnormality who attended our department over a 15-year period. Each patient's mutation and clinical features, as well as surgical interventions and sequelae, were recorded.
Results: Eleven patients were identified. Eight cases were familiar (corresponding to two families) and three cases were sporadic. *TWIST1* point mutations were found in ten cases and one had a 7p21.2-p15.3 deletion. The

clinical phenotype was highly variable. Craniosynostosis was confirmed in most cases (mostly bi- or uni-coronal; but complex craniosynostoses were reported in 3 cases). Half presented the classic craniofacial dysmorphism. In one case, only mild ear abnormalities were detected. One sporadic case was detected prenatally and resulted in an early termination of pregnancy. Five patients had received surgical intervention. Learning difficulties and/or developmental delay were found in five patients and hearing loss in three. Intracranial hypertension and ophthalmologic complications were not common.
Conclusion: Our patients displays an extreme intra- and inter-familiar variability. Many cases may be mild and not identified before the birth of a more severely affected child. Molecular testing is recommended for genetic counseling and detection of at-risk relatives.

Primary focal segmental glomerulosclerosis (FSGS) is a clinicopathological entity characterized by sclerotic glomerular lesions and isolated proteinuria or steroid-resistant nephrotic syndrome. The recent identification of causative podocyte gene mutations in familial forms of FSGS, some of which are associated with various extra-renal features, has helped decipher the glomerular filtration barrier pathophysiology. LMX1B mutations lead to Nail-Patella syndrome (OMIM#161200), characterized by dysplasia of the patellae, nails and elbows, and FSGS with specific glomerular basement membrane lesions by electron microscopy. Using a combination of linkage analysis and exome sequencing, we unexpectedly identified a novel LMX1B mutation segregating with the disease in a pedigree of 5 patients with autosomal dominant FSGS but no glomerular basement membrane anomaly suggestive of Nail-Patella-like renal disease by electron microscopy, and no extra-renal features. Subsequently, we screened 73 additional unrelated families with FSGS and found mutations of the same residue that segregate in 2 families. LMX1B encodes a homeodomain-containing transcription factor that is essential during development. To make functional predictions, we mapped the mutated residue onto a LMX1B in silico homology model. This residue is predicted to belong to a homeodomain. The model suggests this residue plays an important role in strengthening the interaction between the LMX1B homeobox domain and DNA molecule. Both mutations are expected to diminish such interactions. This novel finding demonstrates that isolated FSGS could be due to mutations in genes also involved in syndromic forms and highlights the need to include these genes in all next-generation sequencing diagnosis approaches in FSGS.

Abstract
The development of bladder tumors has been associated with a number of causative agents, including schistosomiasis. Schistosome-related bladder tumors show different epidemiological, histopathological, and clinical characteristics compared with non schistosome-related bladder cancers, occurring in younger patients, and being predominantly of squamous cell type.
The present study was carried out to investigate whether there are significant genetic differences between schistosome transitional and squamous subgroups of bladder carcinoma. We have used dual color FISH to determine the cellular copy number of three recognized tumor-related genes (HER-2/neu, MYC, and p53) in relation to chromosomes 8 and 17 centromeres in 75 Egyptian patients with schistosomal associated bladder carcinoma. Forty-one of these tumors were squamous cell carcinomas; the remaining 34 were of transitional cell carcinoma.
Our results demonstrated that, different histological subgroups of bladder tumors are characterized by distinct patterns of genetic alterations. Transitional cell carcinoma showed 1.54 and 2.02 times of Her-2/neu and c-myc gene amplification respectively as squamous cell tumors. For p53, TCC showed 0.67 times susceptible to p53 deletion as the SCC group.
The genetic changes found in transitional cell group are similar to those reported in the non-schistosome-related transitional cell tumors, but differ from tumors exhibiting squamous differentiation.

Simpson-Golabi-Behmel syndrome (SGBS) -OMIM 312870- is a rare X-linked inherited overgrowth syndrome caused by mutation in GPC3 or GPC4 gene. Affected patients present a variable phenotype with pre- and post-natal macrosomia, distinctive facial dysmorphism and numerous congenital anomalies such as diaphragmatic hernia, heart defect, renal defect, genito-urinary tract malformations, gastrointestinal abnormalities, skeletal and hands abnormalities Intelectual disability is not constant. About 10% of patients have an increased risk of developing embryonic tumors in early childhood. Only one case of biliary disease (choledocal cyst) has been described.
GPC3 is localised on Xq26 and encodes for Glypican-3 protein, a glycosylphosphatidylinositol-linked cell surface heparin sulphate proteoglycan
We report here a SGBS patient, who harbours a GPC3 mutation, with neonatal liver disease, and who developed an early biliary cirrhosis. Liver transplantation was discussed, together with the risk of cancer and developmental delay, and successfully performed when he was 19 months old.

Sirenomelia in Cali, Colombia.

W. Saldarriaga, *C. Isaza de Lourido, J. Ramirez;*
Universidad del Valle, Cali., Colombia.

Sirenomelia is a very rare limb anomaly in which the normally paired lower limbs are replaced by a single midline limb, with a prevalence of 0.98 per 100,000. One hospital in the city of Cali, Colombia, of the ECLAMC (Latin-American Collaborative Study of Congenital Malformations) network, reported the unusual occurrence of 4 cases of sirenomelia within a 55-day period in 2005. The follow-up to 2013, shows 4 new cases from that state, in 483,524 births, yielding a prevalence of 0.83 per 100,000 births in the following years. It further describes the characteristics of the cases: according to the Foster Classification 4 Were Dipus, 2 unipus and 2 Apus; according to Stocker and Heifetz Were Clasification 2 type I, 1 type III, 1 type IV, 1 type V, 3 type VI; 3 of cases had other anatomical defects; none of the studied cases had chromosomal abnormalities. Conclusion. The findings suggest that the first 4 cases were a cluster of sirenomelia in Cali, Colombia. We report 8 cases of sirenomelia, a rare congenital defect.

P02.122

Novel phenotypic features associated with increased dosage of SOX3

T. Y. Tan[1,2], *B. Shugg*[3,4], *P. G. Farlie*[2,5], *T. Burgess*[1];
[1]*Victorian Clinical Genetics Services, Melbourne, Australia,* [2]*Murdoch Children's Research Institute, Melbourne, Australia,* [3]*Department of Paediatrics North West Area Health Service, Burnie, Australia,* [4]*University of Tasmania, Burnie, Australia,* [5]*Department of Paediatrics University of Melbourne, Melbourne, Australia.*

SOX3 belongs to the Sry-related-HMG-box-containing group of transcription factors critical in vertebrate development. SOX3 plays a key role in the development of the hypothalamic-pituitary axis and gonadal differentiation. Disruption of SOX3, either by direct involvement or copy number variation of its regulatory region, has been implicated in several human conditions. Duplications of chromosome Xq27.1 involving the SOX3 gene result in X-linked panhypopituitarism in males, with some phenotypic variability depending on the extent of the copy number change. Additionally, duplications of the regulatory region surrounding SOX3 have been observed in patients with XX male sex reversal. We present a boy with partial absence of the corpus callosum, dyslalia, mild developmental delay, divergent strabismus and bilateral retinal colobomas associated with a complex duplication/triplication of chromosome Xq27.1 involving only the SOX3 gene. His mother, a carrier of the SOX3 change, has normal intellect and development, but also had bilateral retinal colobomas and mild dyslalia. This is the first time a CNV involving SOX3 has been reported with an ocular phenotype. This may suggest that ocular development is more tolerant of SOX3 dosage changes than the hypothalamus and pituitary gland. Our data are consistent with Sox3 transgenic animal models and underscores the importance of Sox3 dosage in the development of the brain, eyes and hypothalamic-pituitary axis.

Toulouse III, UMR1027 Epidémiologie et analyses en santé publique, risques, maladies chroniques et handicap. Equipe 4 : Génomique, biothérapie et santé publique : approche interdisciplinaire, Toulouse, France.*

Syndromic obesity is defined by the association of obesity (BMI>30 in adults and above IOTF 30 chart in children) with one or more abnormalities including predominantly developmental delay, dysmorphic features and/or congenital malformations. Over 25 syndromic forms of obesity have been identified. However, most of cases remain of unknown etiology. The aim of this study was to identify new candidate loci associated with syndromic obesity in order to trigger new candidate genes and to better understand molecular mechanisms involved in this pathology. To achieve our objectives, we performed high-density oligonucleotide array-CGH in a cohort of 89 children presenting with syndromic obesity of unknown etiology, after exhaustive clinical, biological and molecular studies. Chromosomal aberrations were detected in 36/89 children (40%) occurring throughout the genome. Considering aberrations greater than 500 kb, this rate was reduced to 19/89 (21%). Among the entire cohort, only 4/89 (4.5 %) had *de novo* anomalies. However, we could not exclude every inherited anomaly as some of the parents carriers presented with obesity and/or intellectual disability. Even if no recurrent locus was identified (except for the 16p11.2 locus), our results further support that chromosomal rearrangements are more frequently associated with syndromic obesity with a variety of contributory genes having relevance to either obesity or developmental delay. Pathogenicity is however difficult to assert in these disorders suspected to be multifactorial. In conclusion, these findings show the importance of array-CGH in the etiological diagnosis of syndromic obesity allowing an appropriate genetic counseling in some families.

A rare combination of Syntelencephaly, Hemiparesis and Wormian bone

A. Koparir[1], *H. Aydin*[1], *E. Koparir*[1], *H. Ulucan*[1], *E. Yosunkaya*[1], *M. Seven*[1], *A. Yüksel*[2], *M. Özen*[1];
[1]*Istanbul University Cerrahpasa Medical School Department of Medical Genetics, Istanbul, Turkey,* [2]*Bezmialem Vakif University, Istanbul, Turkey.*

Syntelencephaly is a rare anomaly characterized by fusion of the hemispheres in the posterior frontal and parietal regions and is considered a new variant of holoprosencephaly.
Wormian bones are accessory bones that occur within cranial suture and fontanelles, most commonly within the posterior sutures. They occur more frequently in disorders that have reduced cranial ossification, hypotonia or decreased movement, thereby resulting in deformational brachycephaly.
Here, we report a one-week- old male who presented with abnormal head shape and concern for craniosynostosis. He had brachycephaly, alopecia, right hemiparesis and closed anterior fontanelle. Three dimentional CT scan revealed absence of the anterior fontanelle, sagittal wormian bone and split metopic suture. Alopecia was noted in the skin overlying the wormian bone. MRI scanning showed deficient formation of the interhemispheric fissure with fusion of parietal lobes and agenesis of corpus callosum. We designed an array which includes 44K ISCA probes covering whole genome and 14,217 additional probes for intronic and exonic regions of the all known 226 skeletal dysplasias genes. We detected no significant copy number changes in our patient. To our knowledge, there is no published report showing syntelencephaly with wormian bone referring our case as the first report in this rare combination.

Ectrodactyly in Townes-Brocks syndrome: expanding the phenotype to limb abnormalities

A. Guerrot[1], *G. Pinto-Cardoso*[2], *T. Hazelzet*[3], *F. Louillet*[3], *Y. Lerosey*[4], *I. Gilles*[5], *S. Manouvrier*[6], *F. Escande*[7], *T. Frebourg*[1,8], *S. Abu Amara*[9], *A. Goldenberg*[1];

Townes-Brocks syndrome (TBS) is a variable autosomal dominant condition characterized by external ear anomalies with hearing loss, hand anomalies, and anorectal malformations. Other features are renal and urogenital anomalies, cardiac malformations, mild feet anomalies and intellectual disability has been reported in some cases. We report a patient with bilateral split feet. Other abnormalities included long and thin thumbs, anal imperforation, renal hypoplasia with cysts, and bilateral preauricular tags. A ventricular septal defect and a profound bilateral deafness were subsequently identified. Townes-Brocks syndrome was suspected on the association of renal, auricular, anal and hand abnormalities, although ectrodactyly is usually not a feature in TBS. A de novo SALL1 mutation, c.826 C>T, leading to a premature stop codon, was indeed identified, confirming therefore the TBS diagnosis. To our knowledge, ectrodactyly has only been described once in TBS (Van Bever et al, 2009). This description of the second case of ectrodactyly in a TBS patient confirms that the diagnosis of TBS should be considered when such limbs abnormalities are associated with other classical features of the syndrome.

Necker University hospital, Paris, France.*

We report on a series of 12 patients presenting with Townes-Brocks syndrome (TBS) and *SALL1* mutations.

TBS is an autosomal dominant Multiple Congenital Anomalies (MCA) condition. It is classically characterized by a triad associating dysplastic ears and/or hearing loss (90% of cases); thumb anomalies (81%) and anal defects (68%). Other features may include foot anomalies (50%), renal and genitourinary malformations (39%) and congenital heart defects (12%).

SALL1 encodes a zinc finger transcriptional repressor implicated in heterochromatin-dependent silencing process.

Here we report on 12 patients (3F/9M from 10 families) with identified *SALL1* mutations and very variable phenotypes. Most mutations (8/10) are novel. Two index patients carry the recurrent Arg276X mutation. The typical triad was found in only 50% cases (6/12). However 100% had ears anomalies (12/12), which were unilateral in 2 patients. Other malformations were thumb malformations (7/12 = 58%), anal (6/12 = 50%), renal (6/12 = 50%) and cardiac (1/12 = 8%) defects. Feet anomalies were observed in 4 cases (33%).

Furthermore one female patient underwent pregnancy termination because of renal agenesis/dysplasia with oligohydramnios in her fetus.

We confirm in this series that *SALL1* mutations cause a range of very variable phenotypes. However, in our series dysplastic or malformed ears and/or hearing loss were constant, even if very mild in some cases. We conclude that ears have to be carefully examined in patients with either anal or renal malformations, and that TBS have to be considered event if the classical triad is not fully present.

Large segment pure trisomy 3q resulting from a familial 3;14 balanced translocation

L. S. Penney[1], *L. M. Currie*[2];

[1]*Department of Pediatrics, Dalhousie University, Halifax, NS, Canada,* [2]*Maritime Medical Genetics Service, IWK Health Centre, Halifax, NS, Canada.*

Partial trisomy 3q has been reported in the literature on many occasions but less frequently without additional chromosomal abnormalities. Cases typically involve 3q21 to qter with a proposed critical region of 3q26.3 to 3q29 with the resulting phenotype including facial dysmorphisms, microcephaly, heart defects, genitourinary abnormalities, malformations of the extremities, intellectual disability and growth failure.

Here, we report on a prenatally detected case of pure, partial trisomy 3q involving 3q13.2 to qter [46,XY,der(14)t(3;14(9q13.2;p13) in a pregnancy of a woman known to be a balanced translocation carrier [46,XX,t(3;14)(q13.2;p13)]. A prenatal ultrasound identified numerous abnormalities including an increased nuchal translucency, symmetrically small growth, a complex heart defect, a bilateral cleft lip and palate, hypospadias, a small stomach bubble and a small cerebellum. The male baby was born at 38.5 weeks by a spontaneous vaginal delivery. The prenatal abnormalities were confirmed postnatally and the heart defect was confirmed to be Tetralogy of Fallot with pulmonary stenosis. The genitalia were ambiguous and the testes were not identifiable on ultrasound. Additional findings included hip dysplasia, unusual hands and feet, dysmorphic facies, anemia and thrombocytopenia. The child survived to 2.5 months of age.

To our knowledge, this is one of the few reported cases of partial trisomy 3q involving such an extensive segment of 3q and the only case reported in more recent literature. Additionally, it is one of the few reported cases of pure trisomy 3q. The phenotype reported here is consistent with previous reports, providing further evidence for a predictable partial trisomy 3q phenotype.

Unexpected exome sequencing result: *De novo* trichorhinophalangeal syndrome type I (TRPS I) mutation in an infant with congenital scoliosis, mild developmental delay, and history of consanguinity. A clinical diagnostic problem solved by this new technique

Y. Lacassie[1], *I. Casci*[2], *W. K. Accousti*[3];

[1]*Department of Pediatrics, Louisiana State University Health Sciences Center, New Orleans, LA, United States,* [2]*Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA, United States,* [3]*Department of Orthopaedics, Louisiana State University Health Sciences Center, New Orleans, LA, United States.*

We report a 7½ mo WF with congenital scoliosis, a family history of consanguinity and physical findings which raised suspicions of an autosomal recessive disorder. However the exome sequencing showed an unexpected autosomal dominant syndrome. The proband was considered normal until age 5m when congenital scoliosis with some developmental delay and GER was detected. Good growth, wide face, nevus flammeus in forehead, prominent philtrum, epicanthus and tendency to telecanthus, minor syndactyly toes 2-3, and RL in the right 3rd finger were found.

The exome sequencing demonstrated that the proband has a *de novo,* previously unreported, single nucleotide missense mutation in exon 5 of the *TRPS1* gene (c.2627 C>T). The result of this mutation is a phenylalanine replacing the normal serine at position 876 (p.S876F) of the TRPS1 protein. This transition, from a polar serine to a non-polar, aromatic phenylalanine, may affect the function of one of the protein's two nuclear localization signals (NLSs). This signal is located ten residues away from the mutation. Rossi et al. (2007) reported a missense mutation within the other TRPS1 NLS of a patient with mild TRPS I. The mutation prevented the TRPS1 protein (a transcription factor) from being transported into the nucleus, reducing the amount available for transcription initiation. We hypothesize that our patient has a similar situation. However, since the mutation is not within the NLS, it is hindering transport into the nucleus to an even lesser extent, producing an even milder phenotype without the classical features of TRPS.

P02.129

A case of non-penetrance in an 8-year-old with a pathogenic TSC2 mutation: re-thinking the spectrum of TSC associated disease

L. Badalato, *J. E. Allanson, S. M. Nikkel;*

Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada.

Tuberous sclerosis complex (TSC) is an autosomal dominant genetic condition with widely variable expressivity, and is generally considered 100% penetrant. Here, we present a three-generation family in whom a novel 2bp deletion in TSC-2 was found following the diagnosis of a proband. Six family members tested positive for the deletion. Of these, five showed either clinical or radiographic features of TSC, although only one met full diagnostic criteria aside from the proband. One family member - an 8-year-old boy - showed non-penetrance of TSC features after thorough evaluation, including MRI brain, echocardiogram, abdominal ultrasound, and full dermatologic and ophthalmologic exams. This example adds to the growing body of literature suggesting a broader spectrum of TSC associated disease than was previously appreciated, and presents the second reported case of non-penetrance of TSC in an individual with a familial pathogenic mutation after a full diagnostic workup. These findings illustrate the importance of molecular testing for all first-degree family members of individuals with known TSC mutations, even in the absence of clinical or radiographic findings. A positive result necessitates further screening for TSC related complications in these individuals, and allows for appropriate genetic counseling.

Buzzi" Children's Hospital, Istituti Clinici di Perfezionamento, Milano, Italy,* [5]*Neurology Unit, „V. Buzzi" Children's Hospital, Istituti Clinici di Perfezionamento Milano, Milano, Italy.*

In recent years, improvements in prenatal ultrasound screening techniques have led to increasingly early detection of foetal cardiac tumors. After their diagnosis appropriate multidisciplinary counselling to parents should be

made available to explain prognosis, management options and perinatal treatments. Counselling may be challenging after a diagnosis of foetal cardiac rhabdomyomatosis, for its frequent association with tuberous sclerosis complex (TSC). Thus when foetal cardiac tumors are detected, an additional diagnosis of TSC have to be searched, and TSC1 and TSC2 gene analysis could be prompted up.
From then on, in the absence of any other signs, only careful and periodic evaluations could allow to determine whether the cardiac tumor is isolated or is associated with TSC.
But even in newborns the diagnosis of TSC may be confounded: many findings traditionally regarded as among the most specific for TSC become apparent only in late childhood or adulthood, limiting their usefulness for early diagnosis. In the absence of an overt TSC diagnosis it is therefore essential to begin a regular schedule of follow up examinations, aimed at recognizing the onset of typical signs of TSC and to diagnose possible complications which might otherwise escape notice.
We propose, starting from the description of two illustrative cases, a protocol for a follow up, which includes a complete evaluations at birth and one years of age, followed by neurological yearly examination until age 5, when a comprehensive clinical and instrumental negative revaluation can allow to considered negligible the risk of developing other signs of the condition.

Loss of function of the E3 ubiquitin-protein ligase UBE3B causes Kaufman oculocerebrofacial syndrome

E. Flex[1], *A. Ciolfi*[1,2], *V. Caputo*[2], *V. Fodale*[1], *C. Leoni*[3], *D. Melis*[4], *M. Bedeschi*[5], *L. Mazzanti*[6], *A. Pizzuti*[2], *G. Zampino*[3], *M. Tartaglia*[1];
[1]*Istituto Superiore di Sanità, Rome, Italy,* [2]*Università Sapienza, Rome, Italy,* [3]*Università Cattolica del Sacro Cuore, Rome, Italy,* [4]*Università Federico II, Naples, Italy,* [5]*Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy,* [6]*Università degli Studi di Bologna, Bologna, Italy.*

Kaufman oculocerebrofacial syndrome (KOS) is a developmental disorder characterized by reduced growth, microcephaly, ocular anomalies (microcornea, strabismus, myopia, and pale optic disk), distinctive facial features (narrow palpebral fissures, telecanthus, sparse and laterally broad eyebrows, preauricular tags, and micrognathia), mental retardation, and generalized hypotonia. KOS is a rare, probably under-recognized condition, with less than ten cases reported to date. Here we investigate the molecular cause underlying KOS.
We used an exome sequencing approach on a single affected individual of an Italian consanguineous family coupled to mutation scanning by Sanger sequencing on a second unrelated subject with clinical features fitting the disorder.
Exome sequencing identified homozygosity for a novel truncating mutation (c.556C>T, p.Arg186stop) in *UBE3B*, which encodes for a widely expressed HECT domain E3 ubiquitin-protein ligase. Homozigosity for a different nonsense lesion affecting the gene (c.1166G>A, p.Trp389stop) was documented in the second affected subject, supporting the recessive mode of inheritance of the disorder. Mutation scanning of the entire *UBE3B* coding sequence on a opportunely selected cohort of subjects with features overlapping, in part, those recurring in KOS did not reveal disease-causing mutations, suggesting phenotypic homogeneity of *UBE3B* lesions.
Our data provide evidence that KOS is caused by UBE3B loss of function, and further demonstrate the impact of misregulation of protein ubiquitination on development and growth. The available clinical records, including those referring to four *UBE3B* mutation-positive subjects recently described as belonging to a previously unreported entity, which fit KOS, document the clinical homogeneity of this disorder.

Natural course of Weaver syndrome : about two cases

M. Irabe[1], *L. Houdon*[2], *D. Dubois*[3], *M. Linard*[4], *J. C. Ruzic*[5], *K. Tatton-Brown*[6,7], *N. Rahman*[6], *M. L. Jacquemont*[1];
[1]*Unité de Génétique Médicale, CHU la Réunion, Saint Pierre, France,* [2]*Service de Pédiatrie, CHU la Réunion, Saint Pierre, France,* [3]*Centre d'Action Médico-Sociale Précoce, Saint Louis, France,* [4]*Service d'Imagerie, CHU la Réunion, Saint Pierre, France,* [5]*Service de Chirurgie Infantile, CHU la Réunion, Saint Pierre, France,* [6]*Division of Genetics & Epidemiology, Institute of Cancer Research, Sutton, United Kingdom,* [7]*Medical Genetics, St George's University of London, London, United Kingdom.*

Weaver syndrome is a rare, mostly sporadic, overgrowth syndrome characterized by prenatal onset overgrowth, macrocephaly, typical face, frequent mild intellectual impairment and marked advanced bone age. EZH2, the gene primarily involved in this syndrome, was recently identified [Tatton-Brown et al. (2011); Oncotarget 2:1127-1133]. Since the first delineation by Weaver et al. in 1974, approximately 50 patients have been reported. Twenty-three of them have been ascertained by genetic studies. For most of them, clinical features are not detailed and no follow-up data are available.
We report here on phenotypic evolution from birth of 2 sporadic cases of Weaver syndrome in patients originating from Reunion Island harbouring a different EZH2 mutation, and describe previously unreported features.
Case 1 was born with 3 parameters above the 97th centile, in a context of gestational diabetes. She is now 2 years old, has typical overgrowth, hypertelorism, retrognathism and advanced bone age. She has normal neurological development.
Case 2 was born with normal weight and height, macrocephaly and arthrogryposis. She subsequently developed generalized overgrowth with advanced bone age and mild learning disability, which evoked the diagnosis of Sotos syndrome. By her teens, we observe a normalization of her growth parameters and bone age. She is now 14 years old. Atypical findings are bifid uvula, sandal gap, abnormally shaped teeth and multiple fractures despite normal calcium metabolism.
Frequency of the disease on Reunion Island (2 cases out of 839 500 inhabitants), the possibly normal final height, and inconstant intellectual disability together suggest an underestimation of Weaver syndrome.

Oral-facial-digital syndromes (OFD) are characterized by malformations of the face, oral cavity and extremities. Various forms give rise to clinical differentiation in 13 subtypes. While OFD I presents with an X-linked dominant mode of inheritance and lethality in males, other subtypes occur sporadically or with autosomal recessive transmission. To date, a causative gene has only been found for OFD I with the OFD1 ciliary gene. In order to determine the molecular basis of OFD syndromes, we performed exome sequencing on 16 OFD cases: 2 OFD II, 8 OFD VI, and 6 unclassified types (4 with cerebellar hypoplasia, 1 with severe microcephaly, 1 with chondrodysplasia), combined with homozygosity mapping in 4 consanguineous families. Causative mutations in 4 genes were uncovered in 11 out of 16 cases.
First, we found two OFD1 mutations undetected by Sanger sequencing in two patients with cerebellar hypoplasia. We also identified mutations in 2 genes previously reported in Joubert syndrome, one of them being the major OFDVI disease causing gene (6/8 cases). A novel gene mutated in the patient with chondrodysplasia is involved in intraflagellar transport. Finally, in the patient with microcephaly, we identified a homozygous nonsense mutation in a novel ciliary gene that, similarly to OFD1, binds to the BBSome and localizes to centriolar satellites. Congruently, altering levels of this gene

in a cellular model impacts the pericentrosomal distribution of centriolar satellites.
Altogether these results confirm centriolar satellites dysfunction as a major pathomechanism of OFD syndromes, their large genetic heterogeneity and extensive overlap with other ciliopathies.

Wiedemann-Steiner Syndrome: Expanding the phenotypic spectrum of individuals with MLL mutations, identified through clinician phenotyping versus the DDD project

W. D. Jones[1], *M. McEntagart*[2], *C. Deshpande*[3], *M. Holder-Espinasse*[3], *S. Smithson*[4], *F. V. Elmslie*[5], *K. Tatton Brown*[6], *D. R. FitzPatrick*[7], *D. D. D. Project*[1], *M. A. Simpson*[8];
[1]*Wellcome Trust Sanger Institute, Cambridge, United Kingdom,* [2]*South West Thames Regional Genetics Service, St George's Hospital, London, United Kingdom,* [3]*Clinical Genetics, Guy's and St. Thomas' National Health Service Foundation Trust, Guy's Hospital, London, United Kingdom,* [4]*Department of Clinical Genetics, St. Michael's Hospital, Bristol, United Kingdom,* [5]*SouthWest Thames Regional Genetics Service, St George's Hospital, London, United Kingdom,* [6]*South West Thames Regional Genetics Service, St George's Hospital, London, United Kingdom,* [7]*South East Scotland Clinical Genetics Services Western General Hospital, Edinburgh, United Kingdom,* [8]*Division of Genetics and Molecular Medicine, King's College London School of Medicine, Guy's Hospital, London, United Kingdom.*

In 2000 Steiner & Marques reported a girl with short stature, unusual faces and intellectual disability who developed hypertrichosis cubiti and hypertrichosis of the legs and back. They reported similarities to an individual previously reported by Wiedemann with pre- and post- natal growth deficiency, developmental delay and a distinctive facial appearance. Three further individuals were subsequently reported with a distinctive facial appearance, hypertrichosis and severe developmental delay under the classification of Wiedemann-Steiner syndrome.
In 2012 our group reported that de novo mutations in the histone methyltransferase MLL underlie a distinct phenotype of hypertrichosis cubiti, short stature, intellectual disability and a distinctive facial appearance consistent with a diagnosis of Wiedemann-Steiner syndrome. Other associated features were feeding difficulties, behavioural difficulties, skeletal abnormalities and cardiac defects. However due to the small number of individuals with MLL mutations, information regarding the associated phenotypic and mutational spectrum was limited.
We have screened further individuals for mutations in MLL and recruitment to our study is on going. We have also identified individuals with MLL mutations through the Deciphering Developmental Disorders (DDD) project, which utilises array CGH analysis and exome sequencing in individuals with developmental disorders.
The expansion of the clinical spectrum including detailed information on growth, behaviour and feeding together with the mutational spectrum seen in individuals with MLL mutations will be presented. The phenotype of those individuals identified through non-targeted screening, as part of the DDD project, will be compared with the phenotype of those individuals identified following clinician phenotyping.

Smaller and larger deletions of the Williams Beuren syndrome region implicate genes involved in mild facial phenotype, epilepsy and autistic traits

C. Fusco[1], *L. Micale*[1], *B. Augello*[1], *M. Pellico*[1], *D. Menghini*[2], *P. Alfieri*[2], *M. Digilio*[3], *B. Mandriani*[1,4], *S. Vicari*[2], ***g. merla***[1,5];
[1]*IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy,* [2]*IRCCS Children Hospital Bambino Gesù, Rome, Italy,* [3]*IRCCS Children Hospital Bambino Gesù, San Giovanni Rotondo, Italy,* [4]*University of Brescia, Brescia, Italy,* [5]*University of Trieste, Trieste, Italy.*

Williams Beuren syndrome is a multisystemic disorder caused by a hemizygous deletion of 1.5Mb on chromosome 7q11.23 spanning 28 genes. A few patients with larger and smaller WBS deletion have been reported. They show clinical features that vary between isolated SVAS to the full spectrum of WBS phenotype, associated with epilepsy or autism spectrum behavior.
We describe four patients with atypical 7q11.23 deletions identified by multiple-ligation probe amplification analysis and fine mapping by quantitative real-time PCR. Two carry an approximately 3.5 Mb larger deletion towards the telomere that includes *HIP1* and *YWHAG* genes. Other two carry a shorter deletion of approximately 1.2 Mb at centromeric side that excludes the distal WBS genes *BAZ1B* and *FZD9*, respectively.
Along with previously reported cases, genotype-phenotype correlation in the patients described here further suggests that haploinsufficiency of *HIP1* and *YWHAG* might cause the severe neurological and neuropsychological deficits including epilepsy and autistic traits and that the preservation of *BAZ1B* and *FZD9* genes may be related to mild facial features and moderate neuropsychological deficits. This report highlights the importance to characterize additional patients with 7q11.23 atypical deletions and to compare neuropsychological and clinical features between individuals with larger and smaller WBS deletion to shed light on the pathogenic role of genes within and flanking the Williams Beuren syndrome region.

Atypical interstitial deletion of 7q11.23 containing whole ELN and partial LIMK1: Phenotype comparison with typical Williams syndrome

Y. Muramatsu[1,2], *H. Kakizawa*[3], *K. Shimizu*[4], *H. Ohashi*[4], *S. Hayashi*[5], *J. Inazawa*[5], *S. Mizuno*[1];
[1]*Department of Clinical Genetics, Central Hospital, Aichi Human Service Center, Kasugai, Japan,* [2]*Department of Pediatrics, Nagoya University Graduate School of Medicine, Nagoya, Japan,* [3]*Division of Neurology, Aichi Children's Health and Medical Center, Obu, Japan,* [4]*Division of Medical Genetics, Saitama Children's Medical Center, Saitama, Japan,* [5]*Department of Molecular Cytogenetics, Medical Research Institute and School of Biomedical Science, Tokyo Medical and Dental University, Tokyo, Japan.*

Williams syndrome (WS) is a contiguous gene syndrome commonly caused by a 1.5-Mb deletion involving ELN located at 7q11.23. Over 99% of individuals with WS can be diagnosed using a commercially available fluorescence in situ hybridisation (FISH) probe for ELN and LIMK1. This report documents the case of a 7-year-old girl with a WS-like phenotype. Commercial FISH failed to detect the deletion, but subsequent analysis revealed an atypical interstitial 1.1-Mb deletion of 7q11.23 containing the whole ELN gene and a part of the LIMK1 gene.
She was born of healthy parents at 40 weeks gestation. She had failure to thrive and severe developmental delay. Her craniofacial dysmorphology was slightly different from that seen in WS, but she had a history of peripheral pulmonary stenosis, rectal prolapse, and skeletal features similar to those seen in WS. She also had hyperacusis, tactile hyperesthesia, and extreme fearfulness, but did not have overfriendliness. Her motor, cognitive, and language delays were universal, and at the chronological age of 5 years and 11 months, her developmental age was 1 year and 8 months.
Microarray analysis demonstrated that more genes were involved in the upstream region and were conserved in the downstream region in this case than in cases of typical WS. FISH and microarray analysis should be performed even when an individual shows subtle features of WS. Such analyses will also help define the phenotype-genotype correlation in WS.

P02.137

Williams-Beuren syndrome in the Tunisian population: A cohort of 33 patients

I. Ouertani, *M. Chaabouni, F. Maazoul, M. Trabelsi, L. Kraoua, R. Meddeb, R. Mrad, H. Chaabouni;*
Department of congenital and hereditary disorders, tunis, Tunisia.

Williams-Beuren syndrome (WBS) is a rare multi-system genomic disorder, caused by 7q11.23 microdeletion with a prevalence of 1/7500-1/20,000 live births.
Clinical phenotype includes typical facial dysmorphism (elfin face), mental retardation associated with a peculiar neuropsychological profile and congenital heart defects. Other signs are occasional like ocular, skeletal, renal and dental anomalies.
Here in, we present 33 WBS Tunisian patients. The mean age at diagnosis was 4,7 years. All patients showed facial dysmorphisms.

67% (21/33) have cardiovascular anomaly, supravalvular aortic stenosis (10/21) and peripheral pulmonary stenosis (11/21) are equally found.
Various degrees of mental retardation were present and a normal intelligence was found in a single patient; evaluation of developmental milestones revealed various grades of developmental delay in all the patients younger than 6 years. The unique cognitive profile was found in 15/25 of our patients.
Ocular anomalies (12/33) were less frequent than described, the skeletal anomalies too (10/33). Dental malformations are frequent (23/28).
Idiopathic hypercalcemia was present in 50% of children less than one year (3/6).
WBS is a rare disorder, cardinal signs (facial dysmorphism, mental retardation and cardiovascular defects) were found in our patient n the same proportions than described. The occasional clinical signs have proportion different of precedent reported like hypercalcemia, ocular and dental anomalies.
The identification of the different clinical signs in WBS patients permits to establish a strategy of follow up.

P02.138

Translocation of X;autosome and pattern of X-inactivation

A. M. Mohamed[1], *M. S. Zaki*[1], *A. K. Kamel*[1], *G. Gillesson*[2], *A. Caliebe*[3], *M. Mekkawy*[1], *P. Safwat*[1], *R. Siebert*[3], *I. Mazen*[1];
[1]*National Research cetre, Cairo, Egypt,* [2]*Institut für Humangenetik Lübeck, Universität zu Luebeck, Luebeck, Luebeck, Germany,* [3]*Institute of Human Genetics, Christian-Albrechts-University Kiel & University Hospital Schleswig-Holstein, Campus Kiel,, Kiel, Germany.*

The aim of this study was to correlate genotype/phenotype in Xp terminal deletion and to reveal the pattern of X inactivation in X autosome translocation. We report on a 4 years old girl and presented with developmental delay, seizures and obvious autistic behavior .She had dysmorphic facies and large hairy nevus in her forearm. Her Brain CT showed complete agenesis of the corpus callosum and EEG records showed bilateral epileptogenic focus. She has a karyotype of 45,X,t(X;14)(p22;p11), both parents had normal karyotype. FISH analysis using Xp subtelomere, Shox, XIST gene, and subtelomere 14 revealed Ish t(X;14)(Xpter-,Xp22-). The active centromere belongs to the chromosome 14. Array CGH using Agilent detected a 2Mb loss in Xp22.33 and 4,5Mb gain in Xp22.2p22.12. The deleted region contains 12 genes of which CSFRA and Shox are known as OMIM Morbid Genes. The duplicated region contains 7 OMIM morbid Genes. We used late replicating chromatin technique to detect the pattern of X inactivation. we found that 70% of the translocated X is the inactive one, in the same time the translocated chromosome 14 escape inactivation, while in 30% the normal X is the inactivate one leaving the abnormal X as the active one. The clinical picture may be affected by the haploinsufficiency of the genes that are known to escape X inactivation and lie within the deleted region (Xp22.33), or it is affected by duplicated genes (Xp22.2p22.12) on the abnormal X when it was the active one. We recommend study of gene expression of those genes.

P02.139

Developmental delay , facial dysmorphism and hypotonia in a 9 month old Tunisian girl: a Zellweger-like syndrome?

E. Chabchoub[1], ***I. Chabchoub***[2], *L. Ghorbal*[3], *A. Peeters*[4], *P. P. Van Veldhoven*[4], *J. P. Fryns*[5];
[1]*Department of Immunogenetics, Faculty of Medicine, University of Sousse, Sousse, Tunisia,* [2]*Department of Peadiatric Oncology, University Hospital Farhat Hached, Sousse, Tunisia,* [3]*Department of Radiation therapy, University hospital Habib Bourguiba, Sfax, Tunisia,* [4]*Department of cell metabolism, University of Leuven, Leuven, Belgium,* [5]*Centre for Human Genetics, Leuven, Belgium.*

A 9 month old girl born by caesarean section to non consanguineous Tunisian parents is referred for developmental delay, hypotonia, failure to thrive and dysmorphic features with high forehead, broad nasal bridge hypertelorism and micrognathia. These clinical features are typically seen in the Cerebro-hepato-renal syndrome (also known as Zellweger syndrome(ZS)). However, she had no hepatosplenomegaly. She was hospitalised since birth for recurrent respiratory distress. Brain imaging showed agenesis of the corpus callosum and karyotype was normal. Metabolic investigations showed normal very long chain fatty acids and normal plasmalogen synthesis. No mitochondrial defect could be detected. Transmission electron microscopy did not show abnormal ultrastructural morphological changes of the plasma membrane, endoplasmic reticulum, mitochondria and peroxysomes. No particular deposits were noted in the cytosol and intracellular compartments. The girl died at the age of 20 months after a severe infectious respiratory distress.
Interestingly, similar clinical conditions have been reported (two unrelated Polish children (1) and two sibs born to consanguineous Jewish parents (2)). This highlights the existence of a common genetic defect, more likely to be transmitted in an autosomal recessive pattern, underlying this novel syndrome expanding the spectrum of the Zellweger phenotype.

P03.01

Gene conversion by non-allelic homologous recombination between CRYBB2 and CRYBB2P responsible for autosomal-dominant congenital cerulean cataract in a Bulgarian child

L. T. Balabanski[1], *S. Ivanov*[1], *R. Vujarova*[1], *I. Petkova*[2], *A. Popova*[2], *P. Vasileva*[3], *M. Malinov*[1], *D. Toncheva*[4,1];
[1]*Malinov Clinic, Sofia, Bulgaria,* [2]*Aleksandrovska Hospital, Sofia, Bulgaria,* [3]*Akademik Pashev Hospital, Sofia, Bulgaria,* [4]*Medical University, Sofia, Bulgaria.*

Congenital cataracts are among the most common causes of blindness in children world-wide. We report on a 3-year old Bulgarian girl with an autosomal-dominant cerulean cataract. After obtaining informed consent from her parents, genomic DNA was isolated from blood and was scanned on an Illumina iScan system using a HumanCytoSNP-12 BeadChip as a scanning panel. A large ~200-kb deletion was detected in chromosome 22 encompassing the *LRP5L* gene. Although mutations in the gene that it shares similarity with - *LRP5,* lead to another ophthalmological disorder, familial exudative vitreoretinopathy, it is unlikely that the loss of *LRP5L* itself has resulted in the observed phenotype, as this gene encodes only one of the four extracellular beta-propeller domains of LRP5, and does not have the other functional domains, nor the extracellular signal peptide sequence. *LRP5L* is, however, located just between the *CRYBB2*, mutations in which lead to cerulean cataracts, and the pseudogene *CRYBB2P*, which shares 97% sequence homology to *CRYBB2*. Non-allelic homologous recombination introducing the accumulated mutations of the *CRYBB2P* pseudogene into the sequence of *CRYBB2* would lead exactly to the loss of *LRP5L* situated between them. RT-qPCR analysis of the parents showed that both had two copies of the *LRP5L* gene, while the girl had only one. This proves that gene conversion between the paralogous *CRYBB2* and the pseudogene *CRYBB2P* is the mechanism causing cerulean cataracts, as previously theorised.

P03.02

Identification of Novel Homozygous Deletions in Consanguineous Pedigrees as a Shortcut to Candidate Gene Discovery in Hereditary Blindness

K. Van Schil[1], *T. De Ravel*[2], *B. P. Leroy*[3,1], *H. Verdin*[1], *F. Coppieters*[1], *F. Meire*[4], *E. De Baere*[1];
[1]*Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium,* [2]*Center for Human Genetics, Leuven University Hospitals, Leuven, Belgium,* [3]*Center for Medical Genetics, Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium,* [4]*Department of Ophthalmolgy, Huderf, Brussels, Belgium.*

Purpose: To identify the underlying genetic cause in 25 pre-screened patients of consanguineous origin, diagnosed with autosomal recessive retinitis pigmentosa (ARRP) or Leber Congenital Amaurosis (LCA) using identity-by-descent (IBD) mapping. To demonstrate the power of mapping of homozygous deletions as a shortcut to candidate gene identification in retinal dystrophies (RDs).
Methods: IBD mapping was performed by genome-wide SNP chip analysis, data analysis by PLINK. Deletions were confirmed by conventional PCR, segregation analysis was performed by qPCR.
Results: Homozygous deletions were identified in 3 out of 25 families. The first deletion (133 kb) removes the first non-coding exon of the known gene *EYS*. The second deletion (112 kb) disrupts the last 3 exons of *RERG*. The third one (416 kb) is a partial deletion of *GRID2*, which leads to an in-frame

deletion (p.Gly30_Glu81del).
Non-coding deletions of *EYS* have not yet been described. As to the *RERG* and *GRID2* genes, both are regulated by the transcription factor CRX (Corbo et al., 2010). The *RERG* deletion was found in a homozygous state in unaffected siblings however, whose clinical status needs to be revisited. *GRID2* encodes a neurotransmitter receptor. While a homozygous mutation in mouse was found to be lethal, the in-frame deletion found here might represent a hypomorphic allele.
Conclusions: This study revealed involvement of a homozygous 5'UTR deletion of *EYS* in ARRP, and uncovered potential novel candidate genes for RDs. We demonstrated that homozygous deletion detection in consanguineous families might be a powerful approach for gene discovery in hereditary blindness.

P03.03
Correlation between phenotype and genotype in diabetic retinopathy

*M. J. Simões[1], S. Carmona[1], S. Nunes[2], C. Lobo[2,3], J. Cunha-Vaz[2], C. Faro[1], **C. Egas**[1];*
[1]Genoinseq, Biocant – Biotechnology Innovation Center, Cantanhede, Portugal, [2]AIBILI - Association for Innovation and Biomedical Research on Light and Image, Coimbra, Portugal, [3]IBILI / FMUC - Institute of Biomedical Research on Light and Image / Faculty of Medicine, Coimbra University, Coimbra, Portugal.

Diabetic retinopathy (DR), a microvascular complication of diabetes, is one of the most frequent eye diseases in the world. Different patterns of progression are observed in patients with similar metabolic control and duration of the disease, suggesting the involvement of genetic components.
A case-control association study was performed to identify genetic biomarkers that can predict DR progression in type 2 diabetic patients.
A population of 307 type 2 diabetic patients with DR, followed-up during a 2 years prospective study, was classified in 3 different phenotypes of DR progression (phenotypes A, B, C) based on non-invasive methods.
The genes ACE, AGER, AKR1B1, ICAM1, MTHFR, NOS1, NOS3, PPARGC1A, TGFB1, TNF and VEGFA were chosen as candidates based on literature searches. The SNPs described for these genes were filtered through bioinformatics tools to identify the polymorphisms with a high probability of association with pathogenic traits. The 172 SNPs selected were genotyped in the 307 patient samples using the TaqMan OpenArray Genotyping Platform from Life Technologies. The genotype distribution was analyzed for the 3 phenotypes using the Pearson test and/or the Fisher's exact test. Phenotype A, the one with a lower DR progression, was used as the reference.
Statistically significant differences between the reference and the worst phenotypes were found for SNPs in ACE, AGER and NOS1. The identification of these biomarkers, associated with a more rapid DR progression and vision worsening, could open new perspectives for the clinical management of these patients.

P03.05
USHER Syndrome Clinical Aspects in Spain: Genotype-phenotype correlation of USHA2 gene frequent mutations

***F. Blanco-Kelly**[1], T. Jaijo[2], E. Aller[2], A. Avila Fernandez[1], P. Fernández San José[1], B. García Sandoval[1], A. Giménez[1], M. Corton[1], J. Millán[2], C. Ayuso[1];*
[1]Fundacion Jimenez Diaz, Madrid, Spain, [2]Hospital Universitario La Fe, Valencia, Spain.

Usher syndrome is an autosomal recessive disorder characterized by retinitis pigmentosa and bilateral sensorineural hearing loss with (type I), without (type II) or variable (type III) impairment of vestibular function.
We aim to describe: 1-the cardinal phenotypic characteristics and differences among Usher I and II of a Spanish Usher patients cohort and 2-to perform a phenotype-genotype correlation for most frequent mutations in USHA2 gene.
Methods: 201 unrelated Usher Spanish families (271 patients) were studied using genotyping microarray (Usher, Asper-Biotech) and/or automatic sequencing of Usher genes.
Diagnosis and type classification was based on pedigree data, ophthalmologic, audiological and vestibular examination.
Phenotype (Usher I -N=56- or Usher II -N=215- clear diagnosis patients) and phenotype-genotype correlation for c.2299delG and p.Cys759Phe were assessed.
Results: Frequent USH2A gene mutations, carrier frequencies: c.2299delG=36.9% (31/84) and p.Cys759Phe=15.5% (13/84).
Ages at Diagnosis: Usher I=14.6yr; Usher II=27.4yr; c.2299delG=27.5yr; p.Cys759Phe=34.2yr (p=0.06)
Night blindness onset: Usher I=9.8yr; Usher II=17.8yr; c.2299delG=19.1yr; p.Cys759Phe=25.2yr (p=0.08)
Visual field loss onset: Usher I=11.7yr; Usher II=22.4yr; c.2299delG=21.4yr; p.Cys759Phe=27.7yr (p=0.07)
Visual acuity loss onset: Usher I=13.7yr; Usher II=25.5yr (p<0.00); c.2299delG=24.2yr; p.Cys759Phe=30.7yr
Hearing loss age and severity: c.2299delG=8.5yr; mild 15.4%, moderate 71.8% and profound 12.8%; p.Cys759Phe=29.2yr; mild 45.5% and moderated 55.5%. Onset p<10-4.
Conclusions
Visual and audiological impairment is more severe on Usher type I than on type II, p<10-4 for every item analysed.
c.2299delG associated phenotype is similar to the general phenotype found on Usher II patients. Although is only significant for audiological impairment (p<10-4), p.Cys759Phe seems to be associated with milder Usher II phenotype.

P03.06
Disease mechanism in the Usher syndrome

***S. Dad**[1], N. D. Rendtorff[2], M. Larsen[3], L. Tranebjærg[4], L. B. Møller[1];*
[1]Rigshospitalet-Kennedy Center, Glostrup, Denmark, [2]Copenhagen University, Copenhagen, Denmark, [3]Rigshospitalet-Kennedy Center- Glostrup Hospital-Copenhagen University, Glostrup, Denmark, [4]Copenhagen University- Bispebjerg Hospital, Copenhagen, Denmark.

Aim: To obtain a better understanding of the unknown disease mechanisms, which leads to development of blindness and deafness in Usher syndrome (USH).
Background:.USH is clinically is divided into three types, USH1, USH2 and USH3. To date 9 genes and 3 novel loci have been identified for USH syndrome.
1) At the Kennedy Center we have a database with Usher affected persons and many of these have not been genotyped. We will try to genotype as many as possible by screening the DNA for all known USH mutations.
2) We have a Danish consanguineous family of Dutch descent with 5 affected. We performed homozygosity mapping with SNP array and identified a homozygous region, where all affected were homozygous and the non-affected heterozygous. The region was located at chr 15: 60.51 Mb- 67.84 Mb. Some of this region overlapped both *USH1H* locus, *DFNB48* and *USH2* locus and we screened all the genes in this overlapped region but did not identified any pathogenic variants. We performed then a targeted Next Generation Sequencing of the region and did not identify any mutation either. Exome sequencing has also been performed.
3) For the purpose of making a new treatment with aminoglycoside, which can suppress a premature stopcodon so the translation will continue and a partial functionally protein will be made. We will try this setup with two known USH genes both *in vitro* and *in vivo.*

S. Dad: None. **N.D. Rendtorff:** None. **M. Larsen:** None. **L. Tranebjærg:** None. **L.B. Møller:** None.

P03.07
CYP1B1 mutational screening in a portuguese cohort of primary congenital glaucoma patients

***S. Carmona**[1], M. J. Simões[1], E. Silva[2], C. Egas[1];*
[1]Genoinseq, Biocant – Biotechnology Innovation Center, Cantanhede, Portugal, [2]Department of Ophthalmology, Coimbra University Hospital, Coimbra, Portugal.

Primary congenital glaucoma (PCG), a rare but severe form of glaucoma, is characterized by a high intraocular pressure during the neonatal or early infantile period. If not promptly treated, the optic nerves are irreversibly damaged, causing permanent vision loss.
Mutations in CYP1B1 gene are the major cause of PCG. To determine the incidence and spectrum of CYP1B1 mutations in Portuguese PCG patients, translated and untranslated regions from 29 affected individuals were analyzed by direct sequencing.
Nine disease causing mutations were identified in 69% (20/29) of the patients. CYP1B1 mutations were homozygous in 31% (9/29) and compound heterozygous in 38% (11/29). Found mutations included 5 frameshifts (c880delG, c1410del13, c1546dup10, c1691delG, c1749dup27), 3 missenses (Leu378Gln, Glu387Lys, Pro437Leu) and 1 nonsense (Arg444Term). The c880delG mutation was identified as a predominant CYP1B1 allele

among the Portuguese patients. All mutations segregated with the disease phenotype, being consistent with the autosomal recessive form, described for the disease, in complete penetrance.
Despite the high incidence of CYP1B1 mutations in our patients, 31% (9/29) were negative for mutations in this gene. These patients represent an exciting opportunity to explore alternative pathogenetic mechanisms involved in PCG and, therefore, their whole exomes are now being sequenced.
Since mutations in CYP1B1 gene are the major cause of PCG in the Portuguese population, CYP1B1 mutational screening in PCG patients and at-risk relatives, should be performed as a tool to assist the medical community in the management of this disease. Early diagnosis, along with prompt and surgical intervention, result in better prognosis.

P03.08
Prevalence of RDS peripherin mutations in Tunisian families with autosomal retinal dystrophies

F. Ouechtati[1,2], *K. Baklouti*[1,3], *S. Abdelhak*[2], *L. El Matri*[1];
[1]*Institut Hedi Rais d'Ophtalmologie de Tunis, Bab Saadoun, Tunisia,* [2]*Institut Pasteur, Tunis, Tunisia,* [3]*Hopital Régional, Nabeul, Tunisia.*

Purpose: To evaluate the relevance of RDS gene in Tunisian families displaying an inter- and intra- familial clinical heterogeneity in retinal dystrophies.
Methods: Blood samples were obtained from four families including 12 available patients presenting with 6 retinal dystrophies, and 3 healthy relatives. Each patient underwent a detailed clinical examination. Genomic DNA was extracted from the blood samples and screened for mutations in RDS peripherin gene.
Results: Sequence analysis of the human RDS/peripherin gene led to the identification of five non disease-causing changes Vall06Val, Glu304Gln, Lys310Arg, Gly338Asp and IVS3+15 C>T. None of them could explain the significant phenotypic differences between retinitis pigmentosa, fundus flavimaculatus, bull's eye maculopathy, related Stargardt disease retinopathies and retinitis punctata albescens.
Conclusions: This study showed that RDS mutations have a low prevalence in retinal dystrophies. The frequency of peripherin mutations appears to be similar to Italian (0-1.4%), Indonesian and Japenese populations (0-1.9%). To our knowledge, this is the first report to identify frequencies of RDS mutations in retinal dystrophies patients in Tunisia.

Genome-wide association study in animal model of vision disorders

S. J. Ahonen[1,2,3], *H. Lohi*[1,2,3];
[1]*Department of Basic Veterinary Biosciences, University of Helsinki, Helsinki, Finland,* [2]*Research Programs Units, Molecular Neurology, University of Helsinki, Helsinki, Finland,* [3]*The Folkhälsan Research Center, Helsinki, Finland.*

Purebred dogs suffer from hereditary vision disorders, which resembles corresponding disorders in humans. Our study has focused on the genetics of retinal dysplasia (RD) and vitreous degeneration (VD) in two different dog breeds, American Cocker Spaniel (ACS) and Italian Greyhound (IT), respectively. Both disorders are known to be inherited in the breeds, but the genetic background has remained unknown. Both disorders may cause vision deterioration and secondary complications may include glaucoma, lens luxation and retinal detachment, which in turn may lead to a complete blindness. We have established a large sample cohort for multifocal RD in ACS and for VD in IT. A genome-wide association study (GWAS) was performed using canine specific SNP array to map the associated loci in both disorders.
The GWAS data identified a genome-widely significant association for MRD in ACS on canine chromosome 22 (CFA22) with p_{raw}=1.9*10-5, p_{genome}=0.01 and a tentative association, with a 2 Mb homozygous haplotype, for VD in IT on CFA15 with p_{raw}=5.1x10-5, p_{genome}=0.27. Further replication studies are being performed to confirm and to define the associated regions.
Two novel loci were mapped for two canine vision disorders. Ongoing candidate gene sequencing is likely to open new insights to the molecular background of the studied conditions. The identification of genes behind these disorders will establish a large animal model for the corresponding human disorders and the associated genes can be studied in humans. While the associated genes will become candidates for human studies, a genetic test can be offered for the studied breeds.

Retinitis pigmentosa (RP) is a group of inherited disorders in which abnormalities of the photoreceptors or the retinal pigment epithelium (RPE) of the retina lead to progressive visual loss. RP are genetically heterogeneous disorders caused by more than 40 different genes for isolated RP and more than 50 different genes for syndromic RP.
Mutations in CNGB1 encoding the beta-subunit of the rod cGMP-gated channel are responsible for an autosomal recessive form of RP (RP45). However, mutations in CNGB1 have been reported only three times in the literature.
We studied a 51-year-old patient of French origin affected with an isolated RP and born to consanguineous parents (f = 1/32).
Run of homozygosity (ROH) was done using SNP-array (CytoSNP12, Illumina, with 300,000 markers including 200,000 SNP) in the proband and her 2 healthy brothers. After segregation analysis, the largest LOH that was only present in the affected patient was a 23MB region at chromosome 16q12.1q23 containing CNGB1.
Sequencing of CNGB1 evidenced a homozygous stop mutation, p.W313X.
Until now, only 3 homozygous mutations have been reported in CNGB1: two missense mutations (Bareil et al, 2001;Simpson, 2011) and one frameshift mutation in exon 32 (Kondo et al, 2004; Becirovic, 2010).
The mutation reported here is therefore the fourth pathogenic mutation in CNGB1 and the first unequivocal stop mutation in this gene confirming its implication in RP 45.

P03.11
Isolated dominant familial ectopia lentis and FBN1 mutation: variability of expression and interest in clinical surveillance

E. Halimi[1], *E. Laumonier*[2], *C. Decaesteckere*[1], *N. Hanna*[3], *C. Boileau*[3], *S. Manouvrier*[1], *C. Vincent-Delorme*[1];
[1]*Clinique de génétique médicale « Guy Fontaine », Hôpital Jeanne de Flandre, Lille, France,* [2]*Service d 'Ophtalmologie, Hôpital Claude Huriez, Lille, France,* [3]*Département de génétique, IFR 94 - Institut de Recherche Necker Enfants Malades, Paris, France.*

Most of the time, congenital ectopia lentis (EL) are part of syndromic diseases such as Marfan Syndrome, Homocystinuria, Weill-Marchesani Syndrome, etc. However, in 8% of cases, some can be isolated and are mostly familial. Both inheritance are observed: 64% of them, autosomal dominant, are linked to FBN1 while 18%, autosomal recessive, are linked to ADAMTSL4.
We report the case of a FBN1 mutation associated with a familial isolated EL.
The diagnosis of isolated EL was made in a ten years old propositus, during a routine eye examination. The dominant character of the disease was established through the production of the Pedigree. Therefore, an ophthalmologic examination was performed in the first-degree relatives and FBN1 molecular analysis was performed in the propositus.
A heterozygous missense mutation was identified. This mutation was previously described in another Chinese family by positional cloning. Therefore, this is the first time it is reported in a Caucasian family, using direct FBN1 sequencing. Then, it was researched in relatives at risk of developing an EL, especially in asymptomatic subjects who also received ophthalmologic examination.
Because this affection can go unnoticed to become evident and symptomatic at a variable age, the molecular diagnosis allowed us, in this case, to provide a better surveillance of mutated patients, together with an early detection of EL, then to prevent them from serious complications, and, on the other hand, to reassure non-mutated subjects.

P03.12

Severe Congenital High Myopia Mapped to Chromosome 1.

Y. Perez[1], *L. Gradstein*[2], *O. S. Birk*[1,3];
[1]*The Morris Kahn Laboratory of Human Genetics and the Genetics Institute, Soroka Medical Center, Ben-Gurion University, Beer Sheva, Israel,* [2]*Department of Ophthalmology, Soroka Medical Center and Clalit Health Services, Faculty of Health Sciences, Ben-Gurion University of the Negev, Beer Sheva, Israel,* [3]*Genetics Institute, Soroka Medical Center, Beer Sheva, Israel.*

Myopia is the most common human eye disorder and constitutes a significant public health concern. Specifically, high myopia is a leading cause of visual impairment and blindness worldwide because of its associated ocular comorbidities of retinal detachment, macular degeneration, premature cataract, and glaucoma. We have previously demonstrated that monogenic high myopia can be caused from mutations in LEPREL1, encoding a collagen hydroxylase. Two remotely related consanguineous Israeli Bedouin families presented with an apparently autosomal-recessive phenotype of non-syndromic severe myopia. Using polymorphic markers, homozygosity of affected individuals at loci of candidate genes, including LEPREL1, was ruled out. Genome wide linkage analysis identified a ~4 Mb disease-associated locus on chromosome 1 between rs1970168 and rs636877. Whole exome sequencing of affected individuals is underway.

P03.13

A genome-wide association study provides evidence for association of chromosome 8p23 (MYP10) and 10q21.1(MYP15) with high myopia

W. Meng[1], *J. Butterworth*[2], *D. Bradley*[1], *A. Hughes*[1], *V. Soler*[3], *P. Calvas*[3], *F. Malecaze*[3];
[1]*Queen's University Belfast, Belfast, United Kingdom,* [2]*Newcastle University, Newcastle, United Kingdom,* [3]*Purpan Hospital, Toulouse, France.*

PURPOSE. Myopia is a complex trait affected by both genetic and environmental factors. High myopia is associated with increased risk of sight-threatening eye disorders such as retinal detachment. The purpose of this genome-wide association study was to identify susceptibility genes contributing to high myopia in the French population.
METHODS. High myopic cases were genotyped using Affymetrix SNP 6.0 chips and population controls were selected from GABRIEL French dataset in which samples were genotyped by Illumina Human610 quad array. The association study was conducted using 152,234 single nucleotide polymorphisms that were present on both manufacturers' chips in 192 high myopic cases and 1064 controls to identify associated regions.
RESULTS. Statistical risk associations were found in the 8p23 (MYP10) and 10q21.1 (MYP15) regions. Rs189798 (8p23) and rs11005665 (10q21.1) showed the strongest associations in the associated regions (P=6.64x10-7 and P=2.77x10-5, respectively). The imputed results at 8p23 showed 2 peaks of interest. One region spanned 130kb including rs189798 between MIR4660 and PPP1R3B with the most significant association at rs17155227 (P=1.12x10-10). The second novel peak located in the middle of MIR124-1 and MSRA gene was only 4kb in length with the highest association at rs55864141 (P=1.36x10-7). The peak of the imputed 10q21.1 region was located in the same region as non-imputed dataset between ZWINT and MIR3924, and was 160kb in length with rs3107503 having the lowest P value (P=1.62x10-7).
CONCLUSION. we found that 8p23 (MYP10) and 10p21.1 (MYP15) are associated with high myopia in French population and significantly refined 2 associated loci.

P03.14

Vitamin D receptor signaling and the axial myopia in children

A. N. Voitovich[1], *R. Bannour*[1], *T. S. Razorenova*[2], *V. V. Brzheskii*[1], *V. I. Larionova*[2,3];
[1]*St. Petersburg State Pediatric Medical University, Saint-Petersburg, Russian Federation,* [2]*North-Western State Medical University n.a. I.I. Mechnikov, Saint-Petersburg, Russian Federation,* [3]*St. Petersburg State Pavlov Medical University, Saint-Petersburg, Russian Federation.*

The main reason for myopia in children is the eyeball overgrowth in the anteroposterior direction. The aim of this study was to investigate an association of gene polymorphisms *COL1A1* G-1997T, G+1245T, *VDR* A-3731G, T+61968C, and *APOA1* G-75A, C+83T with the development and severity of axial myopia in children. We examined 53 girls and 24 boys aged 4 to 17 yo: 19 (38 eyes) - with high myopia, 44 (88 eyes) – with medium myopia, and 14 (28 eyes) - with emmetropia. Data of medical history, family history of myopia, ocular tonometry, and A-scan ultrasound biometry were collected for multivariate statistics. RESULTS: The medium myopia was associated with the carrying of *VDR*-3731A-allele and +61968TT-genotype. Also, it was associated with the carrying of *APOA1*-75A-allele, and the female sex. The high myopia was associated with the carrying of *VDR*-3731A-allele, the carrying of *APOA1*-75A-allele, and the carrying of *COL1A1*-1997T-allele. Collagen typeI alpha1 is the main component of the eye sclera matrix, and is known as an eye growth GO-signal. Apolipoprotein A1 is the transporter of cholesterol, a precursor of the $25(OH)_2$vitaminD_3, and is supposed to be a STOP-signal of eye growth. The function of the vitamin D receptor in eye tissues is not clear. But it is known, that receptor activated with $25(OH)_2$vitaminD_3 inhibits indirectly expression of collagen typeI. So, we hypothesize that vitamin D receptor might be a STOP-signal of the eye growth, and *VDR* polymorphism together with vitamin D or ultraviolet deficiency might be a cause of axial myopia in children.

[1]*Medical Genetics Laboratory, Niguarda Ca Granda Hospital., Milan, Italy,* [2]*Pediatric Ophtalmology, Niguarda Ca Granda Hospital., Milan, Italy.*

Since April 2006 a cohort of 216 OCA or OA subjects were recruited from the Medical Genetic Unit and the Department of Pediatric Ophtalmology of the Niguarda Ca' Granda Hospital of Milan (Italy).
TYR, P-protein, TYRP1, SLC45A2 and GPR143 genes, associated to the different phenotypes OCA1, OCA2, OCA3, OCA4 and OA1, have been characterized by sequencing analysis.
Furthermore in order to detect the presence of TYR and P genomic rearrangements (deletion/duplication), MLPA (Multiplex Ligation-dependent Probe Amplification) assay was performed.
After clinical examination and instrumental evaluation by our Ophthalmologic Centre, all patients received a genetic counselling and signed an informed consent.
Up to date the complete analysis of the four genes associated with OCA phenotype was performed on 117 patients. We identified TYR mutations/deletions in 84 patients, P mutations/deletions in 19 patients, TYRP1 pathological alterations in 2 children, SLC45A2 mutations in 5 patients.
Only 7 OCA patients (6%) remained molecularly undiagnosed
We also analyzed for GPR143 gene 8 male patients with a probable OA1 phenotype, possibly X-linked segregating, we found pathological DNA variation in all of them.
The mutations identified in this study are missense and nonsense, small deletions/duplications, splicing defects and gross deletions.
TYR gene sequencing has already been performed on the remaining 91 OCA patients and no mutations have been identified. The analysis of the other genes is currently in progress. Our preliminary results indicate that the OCA1 frequency reaches at least the 40% in our country.

P03.16

Peripapillary Chorioretinal Lacunae in an Autosomal Microdeletion Syndrome

R. Gavrilova, *E. M. Broomall, D. L. Renaud, R. Ghadban, M. C. Brodsky;*
Mayo Clinic, Rochester, MN, United States.

Chorioretinal lacunae (PCRL) consist of well-circumscribed, full-thickness defects of retinal pigment epithelium and choroid, with intact overlying retina. Although pathognomonic for Aicardi syndrome (AS), PCRL are seen in other conditions including microcephaly with chorioretinal degeneration, oral-facial-digital, oculo-auricular syndromes.
AS is characterized by agenesis of corpus callosum, seizures and PCRL. Inheritance is presumed X-linked dominant but causative gene is unknown. We present girl without the classic AS triad who had PCRL due to chromosome 3 microdeletion.
18 month old girl was evaluated for speech, motor delays, staring spells. She was born at 32 weeks gestation to pregnancy complicated by preeclampsia. At birth, was noted to have left hand preaxial polydactyly, atrial-septal defect, pulmonary valvular stenosis. Examination disclosed flat nasal bridge,

epicanthal folds, wide mouth, retromicrognathia, truncal hypotonia. Retinal examination showed bilateral PCRL, which consisted of depigmented areas with variably pigmentated borders, surrounding optic discs. MRI revealed mild thinning of corpus callosum and diffuse hypomyelination.
Genomic hybridization microarray demonstrated 6-megabase interstitial deletion of chromosome 3, spanning 3q21.3 to 3q22.1.
Conclusions: PCRL are not unique to Aicardi syndrome.
AS is thought to arise from gene mutation on X-chromosome. Our patient's large autosomal deletion comprised 66 genes, none known to be associated with chorioretinal lacunae. It is possible that PCRL in our and patients with AS may result from complex gene interactions between the X chromosome and autosomes.
Because our patient had autosomal microdeletion, we recommend chromosomal microarray be performed in patients with PCRL when neurological features do not correspond to those in AS.

P03.17
Early-onset neurological presentation of *OPA1*- associated autosomal dominant optic atrophy with variable expressivity

C. Vinkler[1], *Y. Cohen Rappaport*[2], *E. Leshinsky-Silver*[3], *S. Cohen*[3], *T. Lerman-Sagie*[4], *L. Blumkin*[4], *M. Michelson*[1], *D. Lev*[1];
[1]*Institute of Clinical Genetics Wolfson Medical Center, Holon, Israel,* [2]*Metabolic Nerogenetic clinic Wolfson Medical Center, Holon, Israel,* [3]*Genetics Lab, Wolfson Medical Center, Holon, Israel,* [4]*Pediatric Neurology, Wolfson Medical Center, Holon, Israel.*

OPA1 encodes a protein involved in regulation of mitochondrial inner membrane fusion and cristae remodeling. Mutations in the *OPA1* gene are the most common identifiable cause of autosomal dominant optic atrophy (DOA), which is characterized by childhood-adulthood onset of selective retinal ganglion cell loss, temporal pallor of the optic nerve and a typical color vision deficit with reduced acuity. Dominant optic atrophy plus applies to a subgroup of patients manifesting extraocular neurologic signs.
We describe a girl presenting with infantile onset optic atrophy, developmental delay, ataxia, tremor and hypotonia.
She was born at term to unrelated healthy parents. Her mother noticed abnormal eye movements since early infancy. Strabismus, hypotonia and motor delay were diagnosed at the age of 1y. At 18m optic atrophy, reduced visual acuity, eye lid retraction and developmental delay were diagnosed. At 2y ataxia and tremor were noted . Brain MRI at 4 years showed atrophy of the optic nerve and chiasm.
A known disease causing heterozygous missense mutation A1146G (I382M) was found in the *OPA1* gene by exome sequencing. Her healthy mother and aunt carry the same mutation.
This is a description of an unusually early infantile onset, *OPA1* associated optic atrophy plus, in a girl whose asymptomatic mother carries the same mutation. There is one report regarding early onset severe clinical manifestation of OPA1+ associated with compound heterozygosity for OPA1 mutations. We postulate that a further explanation could be involvement of another gene and epigenetic factors in the mechanism of the disease.

Age related macular degeneration and association of CFH Y402H, rs1410966, LOC387715 A69S, rs11200638 and complement component 3 (R102G) polymorphisms in Turkish Population

Y. Soysal[1], *Ü. U. İnan*[2], *F. M. İçduygu*[1], *A. Akıllı*[1], *N. İmirzalıoğlu*[1];
[1]*Afyon Kocatepe University Faculty of Medicine Department of Medical Genetics, Afyonkarahisar, Turkey,* [2]*Afyon Kocatepe University Faculty of Medicine Department of Eye Diseases, Afyonkarahisar, Turkey.*

Age related macular degeneration (AMD) is a complex multifactorial disease. In this study, it is aimed to establish a relation between single nucleotide polymorphisms of genes (in Complement Factor H (CFH) rs1061170 and rs1410966, in HTRA1 rs11200638 and rs10490924, in C3 gene rs2230199) which are among the suspected genes in AMD disease. 100 healthy control individuals and 199 patients who have long AMD history were involved in this study. Statistically meaningful difference has been observed (p=0.002) between patient and control groups when 183 AMD patients were evaluated for Y402H polymorphism. The difference between groups has been found statistically meaningful for LOC387715 (rs10490924). In our study on RS11200638 , 56.4% GG, 34.3 %AG, 9.3% AA genotypes and GG 26.4 %, AG 47.2 %, AA 26.4% genotypes were determined for patient and control groups, respectively. Evaluations of results have revealed that there is meaningful difference in distruption of genotype for rs11200638 polymorphism between patient and control groups (p=0.0001). But no meaningful difference has been observed for distruption of genotypes between patient and control groups when rs2230199 polymorphism is considered (p=0.981). A meaningful difference has been obtained for distruption of genotypes between patient and control groups for rs1410996 polymorphism (p=0.013). Rs2230199 has given statistically meaningless results in our study on the contrary to the findings obtained for Caucasians. The results that we obtained during this study will be useful for scientific studies which are concentrated on geriatric diseases because of ageing world population in the sense of transferring the data of Turkish population.

P03.19
Investigating the complex genetic architecture of Age-Related Hearing Impairment by a Genome-Wide Association Study in the European population

S. Bonneux[1], *E. Fransen*[1,2], *J. J. Corneveaux*[3], *J. D. Ohmen*[4], *R. A. Friedman*[4], *M. J. Huentelman*[3], *G. Van Camp*[1];
[1]*Department of Medical Genetics, University of Antwerp, Antwerp, Belgium,* [2]*StatUa Center for Statistics, University of Antwerp, Antwerp, Belgium,* [3]*Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ, United States,* [4], *Gonda Research Center for Cell and Molecular Biology,House Ear Institute, Los Angeles, CA, United States.*

Age-Related Hearing Impairment (ARHI) or presbyacusis is the most common sensory impairment in elderly and the leading cause of adult-onset hearing loss. It is a severe social and health problem. ARHI is a complex disease with both genetic and environmental factors contributing to the degeneration of the cochlear cells, but remains poorly studied from the genetic side. To further elucidate the genetic factors for ARHI, we performed a Genome-Wide Association Study (GWAS) using the Illumina CNV370 quad chip and the Illumina HumanOmniExpress BeadChip on 1560 samples, representing the 20% extremes of a population of 2161 Antwerp subjects aged 55-65 years for 3 audiometric phenotypes, as scored by principal component (PC) analysis. We tested association with ARHI by linear regression between each genotype and each PC-score. In addition, we adjusted for environmental factors (PLINK software) and for population stratification (EMMAX software). Previously reported susceptibility genes for ARHI could not be replicated. To more deeply investigate the genetic architecture of ARHI, we executed pathway-analysis (MAGENTA software), examined the role of rare variants per gene (SKAT software) and analysed gene-gene interaction (SIXPAC software). GCTA (Genome-wide Complex Trait Analysis software) estimated that 16 % of the phenotypic variance could be explained by the SNPs analysed in our GWAS. This analysis proves for the first time that ARHI is a highly complex disease, involving many genetic factors with small effect sizes, while there is no evidence for major genetic risk factors with high effect sizes.

[9]Department of Biology, Biology and Geography Faculty, M.K. Ammosov North-Eastern Federal University, Yakutsk, Russian Federation, [10]Institute of Humanitarian Research and Indigenous Peoples of the North, Siberian Branch of the Russian Academy of Sciences, Yakutsk, Russian Federation, [11]Laboratory of Genetic Recombination and Segregation, Institute of Cytology and Genetics, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation, [12]Department of Cytology and Genetics, Novosibirsk State University, Novosibirsk, Russian Federation, [13]Department of Genomics, Institute of Biochemistry and Genetics, Ufa Scientific Centre, Russian Academy of Sciences, Ufa, Russian Federation, [14]Department of Genetics and Fundamental Medicine, Bashkir State University, Ufa, Russian Federation.

Age-Related Hearing Impairment (ARHI 1 and ARHI 2: OMIM 612448, 612976) is one of the frequent sensory disorders registered in 50% individuals to the age of 80 years. ARHI is multifactorial disorder due to environmental and poor-known genetic components. In this study, we present the data on age-related hearing impairment of 48 carriers of mutation IVS1+1G>A (GJB2 gene) and 166 subjects with GJB2-genotype wt/wt in the Yakuts, Siberian population isolate (Eastern Siberia). The GJB2 gene resequencing and detailed audiometric analysis in the frequency range 0.25, 0.5, 1.0, 2.0, 4.0, 8.0 kHz were performed in all examined subjects. Comprehensive molecular and audiological analysis of all individuals allows examination for the presence of genotype-phenotype correlations of mutation IVS1+1G>A and hearing of subjects from examined groups. We revealed the linear dependence between increase of average hearing thresholds at speech frequencies (0.5,1.0,2.0,4.0 kHz) and age of individuals with genotype IVS1+1G>A/wt (r=0.571, p=0.001 for males and r=0.523, p=0.000007 for females). Moreover, the average hearing thresholds on high frequencies (4.0 and 8.0 kHz) in individuals with genotype IVS1+1G>A/wt (both sexes) were significantly worse than in individuals with genotype wt/wt (p<0.05). Age of hearing loss manifestation in individuals with genotype IVS1+1G>A/wt was estimated to be ~ 40 years (r=0.572, p=0.0001). These findings demonstrate that the IVS1+1G>A mutation (GJB2) is associated with age-related hearing impairment (ARHI) of the IVS1+1G>A carriers in the Yakuts.

Mutations in PXDN cause complex microphthalmia, anterior segment dysgenesis, hypotonia and developmental delays

A. M. Slavotinek[1], *R. Lao*[2], *P. Tang*[2], *E. Wan*[2], *T. Bardakjian*[3], *P. Kwok*[2,4,5], *A. Schneider*[3]; *[1]Dept. Pediatrics, University of California San Francisco, San Francisco, CA, United States, [2]Institute for Human Genetics, University of California San Francisco, San Francisco, CA, United States, [3]Division of Medical Genetics, Einstein Medical Center, Philadelphia, PA, United States, [4]Cardiovascular Research Institute, University of California San Francisco, San Francisco, CA, United States, [5]Department of Dermatology, University of California San Francisco, San Francisco, CA, United States.*

Anophthalmia and microphthalmia (A/M) are common birth defects that are significant because of visual loss. Mutations in SOX2 and other genes can cause A/M, but there is high genetic heterogeneity and more than 50% of affected individuals do not receive a molecular genetic diagnosis. We used exome sequencing to study a Caucasian family with two children who had complex A/M with anterior segment dysgenesis, sclerocornea, microphthalmia, developmental delays and hypotonia. The older male sibling had glaucoma. Analysis with ANNOVAR revealed both sibs shared 262 sequence variants. 11 genes had two novel variants and 4 of these genes were expressed in the eye. Sanger sequencing showed two Peroxidasin (PXDN) mutations in both sibs - a maternally inherited nonsense mutation, c.C1021T predicting p.R341* and a paternally inherited, frameshift mutation, c.2375_2397del, predicting premature protein truncation. Mutations in the PXDN gene were previously described in three families with congenital cataracts, microcornea, sclerocornea and developmental glaucoma that had no extraocular anomalies (Khan et al., 2011). The gene is expressed in corneal epithelium and is secreted to the extracellular matrix, thus the eye defects may result from impaired adhesion in the anterior segment or an inability to metabolize reactive oxygen intermediates. Our finding of a broader phenotype for PXDN than previously appreciated is characteristic for exome sequencing, which has proven to be highly effective for mutation detection in “atypical” presentations. We conclude that PXDN mutations should be considered in complex microphthalmia with anterior segment dysgenesis. Khan et al., Am J Hum Genet 2011;89:464.

P03.22

Diagnosis of Bardet-Bield Syndrome by a custom multiplexing mutation panel

J. Sá, *P. Rendeiro, A. Lopes, L. Lameiras, L. Dias, A. Palmeiro, P. Tavares; CGC Genetics, Porto, Portugal.*

Introduction: Bardet-Biedl Syndrome (BBS) is a pleiotropic ciliopathy characterized by inducing alterations in diverse body systems leading to a wide range of clinical features. Its prevalence is estimated at 1/150,000. Its main features are obesity, progressive pigmentary retinopathy, post-axial polydactyly, polycystic kidneys, hypogenitalism, and learning disabilities. Pigmentary retinopathy is always present in adults. Progressive vision loss, some degree of intellectual deficit and obesity can severely impair the life quality of the affected persons. BBS is a genetically heterogeneous disease transmitted in most families as autosomal recessive disease. To date, fourteen genes have been associated with BBS, representing up to 80% of the cases.

Method: We developed a custom multiplex mutation panel (CGC Mutation Panel - Pat. Pending) that contains a total of 129 point mutations identified on the 13 principle genes involved in Bardet-Biedl syndrome: BBS1, BBS2, BBS3/ARL6, BBS4, BBS4, BBS6/MKKS, BBS7, BBS8/TTC8, BBS9/B1, BBS10, BBS11/TRIM32, BBS12 and BBS13/MKS1.

Results: From the 30 samples tested we detected the following mutations on 4 cases:

c.1169T>G (p.Met390Arg) mutation in heterozygosity in the BBS1 gene

c.1015A>G (p.Ile339Val) in heterozygosity was detected in the MKKS gene

c.1169T>G (p.Met390Arg) in homozygosity was detected in the BBS1 gene

c.951+1G>A mutation in homozygosity was detected in the BBS1 gene

Conclusion: This approach is a valuable diagnostics tool, since it detects the most common mutations associated with Bardet-Biedl syndrome. This panel reduces time and costs to achieve a diagnosis and improves its capability, independently of the sample type, allowing an earlier decision-making process in patient management.

Nation-wide genetic screening for patients with bilateral nonsyndromic sensorineural hearing loss (SNHL) in Slovakia

I. Mašindová[1], *L. Varga*[2,1], *M. Hučková*[1,3], *M. Balogová*[1], *& Šuchová*[4], *M. Profant*[2], *I. Klimeš*[1,3], *D. Gašperíková*[1,3];

[1]Institute of Experimental Endocrinology, Slovak Academy of Sciences, Bratislava, Slovakia, [2]I. Otorhinolaryngology Clinic, Faculty of Medicine and University Hospital, Comenius University, Bratislava, Slovakia, [3]Centre for Molecular Medicine, Slovak Academy of Sciences, Bratislava, Slovakia, [4]Department of Phoniatry, University Hospital, Bratislava, Slovakia.

Introduction: Etiology of hearing impairment is very heterogeneous. Approximately 50% of all deaf born cases are attributed to genetic causes. Exact data about genetic etiology of bilateral sensorineural hearing loss in our country are not fully available. Therefore, **the aim of our study** was to carry out the genetic screening for selected genes in patients with bilateral nonsyndromic SNHL throughout Slovakia.

Patients and Methods: Since 2010 we have recruited more than 560 subjects from all boarding schools for children with hearing disabilities in Slovakia and University Hospital in Bratislava. For genetic testing, 418 unrelated individuals with clinically manifested bilateral SNHL were selected and sequenced for *GJB2* gene. In 206 patients, we have also carried out analyses of *GJB6, GJB3* and *POU3F4* genes using the MLPA methodology.

Results: We identified 14 already known mutations, six polymorphisms and one variant in the *GJB2* gene. Homozygous and compound heterozygous mutations were present in 21% and 11% of the subjects, respectively. Proportion of the subjects without having any pathogenic allele, reached 61%. In one individual, a simultaneous occurrence of the 309 kb large deletion in *GJB6* with the *GJB2* mutation was identified. No mutations were found in other genes investigated.

Conclusions: 1. We have established the mutation profile of *GJB2/GJB6* genes in subjects identified across whole Slovakia, and 2. we have confirmed the genetic etiology of hearing impairment in 32% of individuals studied. 3. Our findings serve as key information for genetic counseling and clinical prognosis of SNHL.

Cytokine Genes Polymorphisms and Expression Pediatric Cochlear Implant Patients: No Association with TNF-α (-308), and IL-6 (174), but the IFN-γ (+874) in Associated with the Disease in Turkish Patients

E. Baysal[1], *S. Oguzkan Balcı*[2], *F. Celenk*[1], *M. Kahraman*[2], *M. Deniz*[1], *O. Tunc*[1], *C. Durucu*[1], *S. Mumbuc*[1], *M. Kanlıkama*[1], *S. Pehlivan*[2];
[1]*University of Gaziantep, Faculty of Medicine, Department of Otolaryngology, Gaziantep, Turkey,* [2]*University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey.*

The aim of this study was to explore the association between polymorphisms and expressions of three cytokine genes and clinical parameters in patients in children who underwent cochlear implantation because of congenital profound sensorineural hearing loss.
We analyzed three cytokine genes (IL-6, IFN-γ and TNF-α) in 64 cases with congenital sensorineural hearing loss and in 70 healthy controls. Cytokine genotyping was performed by the PCR-SSP method. All data were analyzed using de Finetti program and SPSS version 14.0 for Windows.
No significant differences were detected between the patient group and the healthy controls with respect to the distributions and numbers of genotypes and alleles in TNF-α and IL-6. However, the TT genotype associated with high expression in IFN-γ and T allel frequency were found to be significantly more frequent in the patients group as compared to the controls (p=0.016, 0.023, respectively).
The relationship between cytokine genotypes/expressions and clinical parameters in patients with congenital hearing loss has not been investigated before. Our results suggest that high expression of IFN-γ gene may be associated with susceptibility to disease. Consequently, IFN-γ may be a useful marker for ethiopathogenesis in patients with congenital sensorineural hearing loss.

Clinical and genetic characteristics of patients with POU3F4 X-linked deafness

R. Birkenhäger*, E. Prera, S. Arndt, W. Maier, R. Laszig, A. Aschendorff;*
Department of Otorhinolaryngology, Head and Neck Surgery, University Medical Center Freiburg, Freiburg, Germany.

Hearing impairment is the most common sensory disorder in humans, affecting approximately one to three in 1000 newborns, with 50 % due to genetic causes. The majority of these cases (70 %) are non-syndromic, about 2 % of these are X-linked. So far five different X-linked loci have been mapped, the causative gene POU3F4 (MIM 300039) has been identified for the gene locus DFNX2. This hearing loss is often progressive, with temporal bone abnormalities and stapes fixation. Temporal bone anomalies include dilation of the fundus of the internal acoustic canal (IAC), that can increase the risk of CSF gusher during stapes or cochlear implant surgery. POU3F4 belongs to a subfamily of transcription factors, which are characterized by two conserved DNA binding domains, a POU and a HOX domain. Several molecular genetic studies have identified mutations in the POU3F4 gene, including partial or complete deletions of the gene, as well as deletions, inversions, and duplications of the DFNX2 genomic region not encompassing the POU3F4 coding sequence. Here we present the clinical characteristics of four patients from independent families. Mutations analysis in the POU3F4 gene was brought by direct sequencing. Sequence analyses revealed a novel deletion of 2600 bp [TAG (Stop) +21nt - 2620nt] and two novel missense mutations c.902C>T, (p.P301L) and c.973 T>A, (p.W325R) and in a fourth patient an already known missense mutation c.907C>T, (p.P303S). Until now three novel strongly conserved mutations in the HOX-domain of the POU3F4 transcription factor were identified leading to an effect in the protein function.

P03.26

A novel mutation (p.Asp171Asn) in wolframin gene, in a patient presenting Low-Frequency Hearing Loss

A. C. Gonçalves[1], ***T. D. Matos***[1], *H. R. Teixeira*[1], *M. Pimenta Machado*[2], *M. Simão*[2], *O. P. Dias*[2], *M. Andrea*[2], *G. Fialho*[1], *H. Caria*[3];
[1]*Centre for Biodiversity, Functional, and Integrative Genomics (BioFIG), Lisbon, Portugal,* [2]*Hospital Santa Maria (Centro Hospitalar de Lisboa Norte, E.P.E.), Lisbon, Portugal,* [3]*School of Health, Polytechnic Institute of Setúbal ; Centre for Biodiversity, Functional, and Integrative Genomics (BioFIG), Faculty of Science, University of Lisbon, Lisbon, Portugal.*

Nonsyndromic sensorineural hearing loss predominantly affecting the high frequencies is a genetically heterogeneous common disorder. On the contrary, low-frequency sensorineural hearing loss (LFSNHL) is an unusual type in which frequencies at 2000 Hz and below are predominantly affected. Most of the families with LFSNHL carry mutations in WFS1 gene that maps to chromosome 4p16 and codes for wolframin, a membrane glycoprotein localized in the endoplasmic reticulum.
A Portuguese NSHL patient was shown to display LFSNHL after evaluation by pure tone audiometry. Blood sample was collected after signing written informed consent. Sequencing of exons 5 and 8 of WFS1 gene was performed after previous testing for mutations in the GJB2 coding exon and for the common GJB6 deletions using sequencing and multiplex-PCR, respectively. One hundred hearing Portuguese controls were sequenced for exon 5.
No mutations were found in GJB2 and GJB6 genes. A novel mutation, c.511G>A, was found in heterozygosity in the exon 5 of the WFS1 gene. At protein level, it causes an alteration of residue 511 of wolframin, occurring in the extracellular N-terminus domain of the protein, by changing an aspartic acid to an asparagine (p.Asp171Asn). This mutation was not present in 100 Portuguese hearing controls.
Since LFSNHL presents a dominant pattern, the auditory phenotype observed in this heterozygous patient might probably be due to the novel mutation p.Asp171Asn. Functional characterization will be performed in order to assess its effect on the mutated protein and to clarify in which way this change leads to LFSNHL.

The SOX10 transcription factor plays a role in the maintenance of progenitor cell multipotency, lineage specification, cell differentiation, and is a major actor in the development of the neural crest. It has been implicated in Waardenburg syndrome (WS), a rare disorder characterized by the association of pigmentation abnormalities and deafness, but SOX10 mutations cause a variable phenotype that spreads over the initial limits of the syndrome definition. Based on recent findings of olfactory bulb agenesis in WS patients, we suspected SOX10 was also involved in Kallmann syndrome (KS). KS is defined by the association of anosmia and hypogonadotropic hypogonadism due to incomplete migration of neuroendocrine GnRH (gonadotropin-releasing hormone)-cells along the olfactory, vomeronasal, and terminal nerves. Mutations in any of the nine causal genes identified to date account for only 30% of the KS cases. KS can be either isolated or associated with a variety of other symptoms including deafness. We report SOX10 loss-of-function mutations in approximately one-third of KS patients with deafness, which defines this gene as the first one with a substantial involvement in this clinical condition. Study of SOX10-null mutant mice revealed a new developmental role of SOX10 in a subpopulation of glial cells called olfactory ensheathing cells. These mice indeed showed an almost complete absence of these cells along the olfactory nerve pathway, as well as defasciculation and misrouting of the nerve fibers, impaired migration of GnRH-cells, and disorganization of

the olfactory nerve layer of the olfactory bulbs.

Exome sequencing and linkage analysis identifies novel N714H mutation in WFS1 as a cause of autosomal dominant hearing loss

A. Pollak[1], *U. Lechowicz*[1], *M. Oldak*[2], *M. Mueller-Malesinska*[1], *L. Korniszewski*[1], *H. Skarzynski*[1], *R. Ploski*[3];
[1]*The Institute if Phisiology and Pathology of Hearing, Warsaw, Poland,* [2]*Department of Histology and Embryology, Medical University of Warsaw, Warsaw, Poland,* [3]*Department of Medical Genetics, Medical University in Warsaw, Warsaw, Poland.*

Hearing loss (HI) is a significant medical problem in Poland and worldwide, occurring in 1 of every 500 newborns. The cause of hearing loss can be genetic or environmental. Currently the background of genetic hearing impairment is an area of intensive research conducted by many groups. Because of more than 40 genes involved in pathogenesis of nonsyndromic hearing loss, it is also an extremely heterogeneous trait. The most common variants responsible for an isolated recessive HI are mutations in the GJB2 gene, but there is no single gene accounts for the majority of cases of autosomal dominant (AD) HI. To date, more than 60 loci of ADHI were mapped, but particular genes were identified for only 25. However mutations in 4 of these genes (WFS1, KCNQ4, COCH, and GJB) are more frequent as a causes of ADHI in comparison to the other.
For searching the reason of HI among family members with AD pattern of inheritance, we performed linkage analysis using Affy 10K chip and exome sequencing on Illumina platform. Data analysis revealed novel N714H mutation in WFS1 gene as a plausible reason for HI. Direct sequencing of fragment of 8th exone of WFS1 gene showed perfect co-segregation between N714H mutation and HI among members of this family. N714H mutation is localized in exon 8, which contains the conserved C-terminal domain. Considering fact that the majority of deafness causing mutations have been identified particularly in exon 8, this domain seems to have a crucial function in the cochlea.

P03.29

Mutations in GJB2 gene - a main cause of non-syndromal hearing loss among Belarus patients

O. Oleinik[1], *M. Siniauskaya*[1], *E. Merkulava*[2], *A. Levaya-Smaliak*[2], *N. Danilenko*[1];
[1]*Institute of Genetics and Cytology, National Academy of Sciences, Minsk, Belarus,* [2]*Belarusian State Medical University, Minsk, Belarus.*

About 50% of congenital non-syndromal hearing loss (SNHL) are caused by mutations in GJB2 gene. The spectrum and frequencies of the GJB2 mutations depend on ethnic origin; in Europe 35delG recessive mutation is the most frequent. According to our previous data, the carrier rate of 35delG in Belarus is twice higher than European average (5.68%). Screening of 391 patients revealed that 35delG is the main cause of SNHL in Belarus: 45.5% were homozygous, 13.1% heterozygous and for 41.4% the major GJB2 mutation was not found.
Among 35delG heterozygotes with SNHL six other mutations in the GJB2 coding exon 2 were found (combining single-strand conformational polymorphism analysis and sequencing methods). However, for 40 patients - 35delG heterozygotes - still only one mutant GJB2 allele was detected while for 139 patients we did not find any exon 2 GJB2 mutations. Therefore, the aim of the present study was to determine still undetected genetic lesions causing SNHL in these patients. We screened them for the mutation IVS1+1G>A in splicing site (5' UTR of GJB2 gene). Mutation IVS1+1G>A was detected in 5 out of 179 patients, that indicates its high frequency. As a result, for five 35delG heterozygote patients the second mutation was detected; thus, the genetic nature of SNHL for them was proved. Moreover, we estimated that for deaf patient cohort IVS1+1G>A is a third most common GJB2 mutations in Belarus, after 35delG and 312del14. The results obtained are necessary for further genetic testing of Belarus patients with non-syndromal hearing loss.

P03.30

Simultaneous Screening of 100 Mutations Associated with Non-Syndromic Hearing Loss in Brazil

M. C. M. Svidnicki, *S. M. da Silva-Costa, P. Z. Ramos, F. T. A. Martins, N. Z. P. Santos, A. M. Castilho, E. L. Sartorato;*
UNICAMP, Campinas, Brazil.

Recent advances in molecular genetics have allowed the determination of the genetic cause of non-syndromic hearing loss, but a large percentage of patients still remain with unidentified cause. It points an imminent need for new methodological strategies for the detection of an increased number of mutations in multiple genes. In this work we screened a set of 100 mutations previously described in 20 different genes, using mass spectrometry system MassArray, Sequenom® followed by Sanger sequencing, to evaluate the contribution of selected changes in the etiology of deafness in Brazil. We analyzed a group of 45 individuals with non-syndromic hearing loss that were previously screened for mutations in main deafness genes, and that showed recessive mutations in *GJB2* and *GJB6* in only one allele. We found additional mutations in two genes: *SLC26A4* and *CDH23*. In the *SLC26A4* were identified two mutations in heterozygous, *p.C282Y* in one individual and *p.V609G* in two other individuals. In *CDH23* two missense mutations were found in different individuals, the *p.R301Q* mutation was found in homozygous, explaining the etiology of deafness, and the *p.R1746Q* was found in heterozygous. These results show that *SLC26A4* and *CDH23* mutations are frequent in individuals with non-syndromic hearing loss in Brazil and emphasize the necessity of considering these two genes for diagnosis. The presence of *CDH23* and *SLC26A4* mutations associated with *GJB2* and *GJB6* mutations might suggest gene interaction, producing deafness in a digenic mode of inheritance, but the point need to be proved in further study.

P03.31

Audiologic characteristics of carriers of a dominant WFS1 mutation

U. Lechowicz[1], *M. Oldak*[2], *A. Pollak*[1], *M. Mueller-Malesinska*[1], *L. Korniszewski*[1], *H. Skarzynski*[1], *R. Ploski*[3];
[1]*The Institute of Physiology and Pathology of Hearing, Warsaw, Poland,* [2]*Department of Histology and Embryology, Medical University of Warsaw, Warsaw, Poland,* [3]*Department of Medical Genetics, Medical University in Warsaw, Warsaw, Poland.*

The WFS1 with chromosomal 4p16.1 position, encodes an endoplasmic reticulum (ER) membrane-embedded protein, called wolframin, which has physiological functions in membrane trafficking, secretion, processing and/or regulation of ER calcium homeostasis. A proper calcium balance plays crucial role in many different cellular functions, including cell-to-cell communication, the tensing (contraction) of muscles, and protein processing. Disturbances in the balance of calcium in the inner ear might interfere with the hearing process.
Mutations in WFS1 gene cause both autosomal dominant low-frequency sensorineural hearing loss (LFSNHL) at the DFNA6/14/38 locus and Wolfram syndrome, characterized by autosomal recessive hearing loss, diabetes mellitus, diabetes insipidus and optic atrophy. The hearing loss caused by dominant WFS1 mutations has been reported to be very characteristic, preferentially affecting the low frequencies without significant influence on the high frequencies.
Using whole exome sequencing we recently found novel WFS1 mutation (p.N714H) segregating in a large family with autosomal dominant HI. The purpose of this study was to evaluate the audiograms in mutation carriers in order to validate the association between WFS1 mutations and low frequency HI. So far we obtained three audiograms. Whereas one of the audiograms was typical with low frequency HI (0.5KHz 45 dB, 8KHz 5 dB) two other were not (0.5KHz 90 dB, 8KHz 70 dB; 0.5KHz 55 dB, 8KHz 120 dB). These data indicate that a flat down-sloping audiograms do not exclude WFS1 defects.

P03.32

Association of Mitochondrial Uncoupling Protein Gene 2 with Congenital Sensorineural Hearing Loss in Pediatric Patients

S. Pehlivan[1], *E. Baysal*[2], *O. Tunc*[2], *M. Nacak*[3], *F. Çelenk*[2], *M. Deniz*[2], *C. Durucu*[2], *S. Mumbuc*[2], *M. Kanlıkama*[2], *S. Oguzkan Balcı*[1];
[1]*University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey,* [2]*University of Gaziantep, Faculty of Medicine, Department of Otolaryngology, Gaziantep, Turkey,* [3]*University of Gaziantep, Faculty of Medicine,*

Department of Pharmacology, Gaziantep, Turkey.

Recently findings suggest that uncoupling proteins (UCPs) may play a protective role against reactive oxygen species in neuron and a thermal signaling role for neuron modulating in vestibular nevre. Uncoupling protein 2 (UCP2) is expressed in inner ear periphery, but the function of UCP2 in inner ear tissues has not been determined yet. The aim of this study was to examine whether UCP2 gene variations are associated with congenital sensorineural hearing loss.

In this study, 64 congenital sensorineural hearing loss children and 80 age and sex matched healthy controls were detected for promoter -866G>A and exon 8 insertion/deletion (I/D) variations of UCP2 gene by using PCR and/or RFLP methods.

Promoter and exon 8 variations of UCP2 gene were showed statistically significant association with congenital sensorineural hearing loss patients. The distribution of II, ID and DD genotypes for the gene was 54.7 %, 26.7 % and 18.6 % in patients compared with 8 %, 30.7 % and 61.3 % in the controls. Insertion homozygote genotype and I allele were found higher in patients ($p<0.0001$). The distribution of UCP2 gene promoter variation GG, GA and AA genotypes was 10.9 %, 45.3 %, 43.8% in patients compared with 21.1 %, 62.5 %, 16.3 % in the controls. Statistically, AA genotype and A allele were found to be increased in patients ($p=0.0003$, $p=0.0010$, respectively).

Our data show that UCP2 gene may play a role for ethiopathogenesis of congenital sensorineural hearing loss. Further studies are needed to elucidate function of UCP2 in sensorineural hearing loss.

P03.33

Genetic aetiology of Hearing Loss in Cyprus

V. Anastasiadou[1], *G. Tanteles*[2], *C. Costi*[2], *C. Shammas*[2], *E. Spanou*[2], *V. Neocleous*[2], *L. A. Phylactou*[2];
[1]*Makarios III Hospital & The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus,* [2]*The Cyprus Institute of Neurology & Genetics, Nicosia, Cyprus.*

Mutations in the *GJB2* (Connexin 26) gene are responsible for more than half of all cases of pre-lingual recessive inherited non-syndromic deafness in Europe. This study presents a mutation analysis of the *GJB2* and *GJB6* genes in 146 Cypriot patients with non-syndromic sensorineural hearing loss (SNHL) compatible with recessive inheritance. Patients were screened for the c.-23+1G>A splice mutation and the coding exon 2 of the *GJB2* gene including also the deletions del*(GJB6-D13S1830)* and del*(GJB6-D13S1854)*. Thirty patients were verified with bi-allelic *GJB2* mutations and with c.35delG as the most dominating one, accounting for 81.7%, followed by p.Arg184Pro (6.7%), p.Leu90Pro (5.0%), p.Glu47stop (1.7%), delGlu120 (1.7%), 167delThr (1.7%) and p.Val178Ala (1.7%).

Ten patients with severe SNHL were also identified with one mutation in the *GJB2* gene only. Interestingly, five of these patients were identified in the heterozygous state with the *GJB2* missense mutation/variant p.Val153Ile, while the rest were identified as heterozygous for p.Val37Ile, c.35delG, p.Leu90Pro, c.-23+1G>A splice mutation and the novel c.-1G>A 5'UTR.

Finally, no *GJB6* mutations or the known del*(GJB6-D13S1830)* and del*(GJB6-D13S1854)* were identified in any of the investigated Cypriot SNHL patients.

This work confirms that the *GJB2* c.35delG mutation is an important pathogenic mutation for hearing loss in the Cypriot population and that the underlying molecular basis of autosomal recessive non-syndromic deafness in Cyprus is genetically relatively homogeneous. This finding will be used towards the effective diagnosis of SNHL, assisting in genetic counseling and used as a potential therapeutic platform.

P03.34

Deep-intronic mutations in OPA1 cause optic atrophy and "optic atrophy plus" phenotypes

T. Bonifert[1], *M. Synofzik*[2], *L. Schöls*[3], *B. Wissinger*[1];
[1]*Molecular Genetics Laboratory, Institute for Ophthalmic Research, Tuebingen, Germany,* [2]*German Research Center for Neurodegenerative Diseases (DZNE), Tuebingen, Germany,* [3]*Department of Neurodegenerative Diseases, Hertie-Institute for Clinical Brain Research, Tuebingen, Germany.*

Inherited Optic Neuropathies (ION) account for about 7% of legal blindness in the European working-age population. Despite the progress in DNA sequencing, still around 55% of all ION cases remain unsolved. This might partly be due to the fact that important ION mutations are commonly missed by exonic sequencing techniques. Here we demonstrate for the first time that deep-intronic mutations in the most common nuclear ION gene OPA1 cause optic atrophy and "optic atrophy plus" phenotypes in so far unresolved ION patients.

Using cDNA analysis of puromycin treated patient-derived fibroblasts of an index family with a severe multisystemic "optic atrophy plus" phenotype, we identified a deep-intronic OPA1 mutation in intron 4b. The mutation creates a novel splice acceptor site, leading to inclusion of a cryptic exon. This aberrant splice product induces frameshift and subsequent nonsense-mediated mRNA decay (NMD) of the mutated transcript. RFLP screening of intron 4b in 369 patients with unexplained ION (negative for exonic OPA1 mutations) revealed 3 further families with deep-intronic mutations around the same site. In the affected siblings of the index family, the intronic mutation occurred in conjunction with a known compound heterozygous mutation (I382M), which explains the observed severe phenotype. The I382M variant acts as a modifier that might be used as a hint for compound heterozygous mutations in non-coding regions of "optic atrophy plus" patients. We conclude that deep-intronic OPA1 mutations might explain a substantial share of so far unexplained cases with optic atrophy or "optic atrophy plus" phenotypes.

Mutations in OPA1, encoding a mitochondrial dynamin-related GTPase, are reponsible for dominant optic atrophy (DOA). About 20% of OPA1 mutation carriers have complicated forms of DOA associating extra-ocular features such as deafness or neuromuscular disorders. Reviewing the files of 327 patients with an OPA1 mutation, we found 21 patients with hearing loss (6.4%). In 10 patients deafness was detected under age 20 (~48%), in 3 patients over age 20 (~14%) and in 8 patients the age of onset was unknown (38%). The severity of deafness ranged from mild and moderate in 14 cases (66%) to profound in 5 cases (24%). Audiological tests supported the diagnosis of auditory neuropathy in 8 cases.

Seven different OPA1 mutations were identified in deaf patients. Three mutations, p.Arg445His, p.Gly401Asp and p.Leu243*, have been previously reported in patients affected with both DOA and deafness. Two mutations, p.Val291_Phe328del and p.Ile463_Phe464dup, have been reported in patients with isolated DOA but not in association with deafness. Finally, two novel OPA1 mutations, p.Arg437Glu and p.Ala357Leufs*4, are implicated for the first time in DOA and deafness. In the majority of patients with DOA and deafness, visual impairment occurred during the first decade while deafness appeared in late childhood or early adulthood. However, in 54% of patients deafness started prior to visual abnormalities indicating that a careful examination of the optic nerves is needed in young patients with post-lingual neurosensorial hearing loss.

These observations suggest that audition should be carefully tested, including a specific search for auditory neuropahy in OPA1 mutation carriers.

Purpose: Leber congenital amaurosis (LCA) is a congenital or neonatal

blindness. The most common disease-causing mutation (>10%) is located deep in intron 26 of the *CEP290* gene where it creates a strong splice donor site that leads to the insertion of a cryptic exon encoding a premature stop codon. Our aim was to assess antisense oligonucleotide (AON)-mediated exon skipping to correct the aberrant splicing.

Material and Methods: Patient fibroblasts harbouring the c.2991+1655 A>G mutation and controls were transfected using antisense and sense 2'O-methyl phosphorothioate oligonucleotides designed to target ESE around the mutation. The efficiency of skipping was assessed using qRT-PCR, Western blot and primary cilia counting.

Results and discussion: *CEP290* Expression levels were unchanged when control cells were transfected using the sense or antisens ONs ($p>0.05$). Likewise, no change was noted when patient cells were treated with the sense ONs ($p>0.05$). Conversely, a highly significant increase in expression of the wildtype *CEP290* allele was obtained when cells were treated with AONs ($0.029<p<0.002$) with expression levels reaching that of controls. Western blot analysis evidenced increased levels of CEP290 in patients' cell lines treated with the AONs but not the sense ONs. Finally, primary cilia expression was significantly reduced in patient's fibroblasts compared to controls lines (48.6%±6.5%*vs*83.6%±3.2%; $p=0.0097$**).** Upon transfection with the antisense ONs but not the sense versions, the proportion of ciliated cells increased significantly in patients, reaching levels similar to controls (75.3%±3.5%*vs*78.3%±3.4%; $p=0.624$). These results show therapeutic potential of exon skipping for the treatment of the most common LCA-causing mutation.

Leber Congenital Amaurosis (LCA) is the earliest inherited retinal dystrophy (RD). Recently, coding mutations in *NMNAT1* resolved the last remaining locus, LCA9 (Falk *et al*. 2012). Here, we aimed to identify the genetic defect in an LCA9-linked consanguineous Sub-Saharan African family (F1) and determine the contribution of *NMNAT1* mutations in LCA.

Massively parallel sequencing of all exons and promotor regions in 4 identity-by-descent regions of F1 identified a novel homozygous 5'UTR variant in *NMNAT1* (c.-70A>T), which segregated with disease. Subsequent *NMNAT1* Sanger sequencing in 76 probands with LCA/early-onset RD revealed coding mutations in 5 additional probands, and identified a second homozygous 5'UTR variant (c.-69C>T) in a Moroccan consanguineous LCA family (F2). In both F1 and F2, cDNA sequencing detected no other potential pathogenic variants but revealed loss of heterozygosity in heterozygous carriers, suggesting *NMNAT1* mRNA degradation. Subsequently, significantly lower mRNA expression in leukocytes was shown for the homozygous mutants in comparison with healthy controls. Luciferase assays for both adjacent 5'UTR variants in COS-7, KGN and COV434 cell lines revealed significantly lower activity for c.-69C>T in comparison with the wild-type 5'UTR. Of note, both families show LCA with evolutive macular involvement, typical for *NMNAT1*-related disease.

In conclusion, this study sustained the role of coding *NMNAT1* mutations in LCA. Moreover, the identification of two neighboring 5'UTR variants in *NMNAT1* makes this the first study to link 5'UTR regulatory mutations to congenital blindness, and may impact upon the role of 5'UTR mutations in hereditary blindness in general.

Broadening the phenotype of LRP2 mutations: association of a new LRP2 mutation with predominantly ocular phenotype suggestive of Stickler syndrome.

G. Van Camp[1], *I. Schrauwen*[1], *M. Sommen*[1], *C. Claes*[1], *M. Flaherty*[2], *F. Collins*[3];

[1]*Department of Medical Genetics, University of Antwerp, Antwerp, Belgium,* [2]*Department of Ophthalmology, The Childrens' Hospital at Westmead, Sydney, Australia,* [3]*Department of Clinical Genetics, The Childrens' Hospital at Westmead, Sydney, Australia.*

We studied two siblings from a consanguineous Iraqi family presenting with a syndrome with high myopia, esotropia, vitreous changes, cataract, , and distinct facial features (epicantic folds, a high nasal bridge and a degree of maxillary hypoplasia).

No mutation was identified in COL9A1/2. To identify the causative mutation, we performed exome sequencing of one of the probands, which revealed a new non-synonymous variant in LRP2 that segregated in the family. The variant (c.11483A>G; p.Asp3828Gly), is predicted damaging according to SIFT and Polyphen prediction programs and is conserved among species. Mutations in LRP2 have been shown to cause the Donnai-Barrow syndrome or Facio-oculo-acoustico-renal (FOAR) syndrome, a syndrome presented with facial abnormalities, ocular anomalies, sensorineural hearing loss, proteinuria, and diaphragmatic hernia and absent corpus callosum, although there is variability in the expression of some features (eg absent corpus callosum and proteinuria). This family shows a milder phenotype with some features and similarities to the Donnai-Barrow syndrome, including demonstrated microglobulinuria. The type of mutation (non-synonymous) might explain the milder phenotype. In conclusion, we have identified a new mutation in LRP2 that broadens the phenotypical spectrum associated with LRP2 mutations.

Introduction: Ciliopathies is an emerging class of genetic disorders due to altered cilia assembly, maintenance or function. Syndromic ciliopathies affecting bone development have been classified as skeletal ciliopathies. Mutations in genes encoding components of the intraflagellar transport (IFT) complex A, that drives retrograde ciliary transport, are a major cause of skeletal ciliopathies. Mainzer-Saldino syndrome (MSS) is a rare disorder characterized by phalangeal cone-shaped epiphyses, chronic renal failure and early-onset severe retinal dystrophy.

Methods and results: We collected 16 families presenting three diagnostic criteria of MSS. Through ciliome re-sequencing combined to Sanger sequencing, we identified *IFT140* mutations in seven MSS families. The effect of the mutations on the IFT140 localization was assessed using flagged-IFT140 mutant proteins which showed a partial to nearly complete loss of basal body localization associated with an increase of cytoplasm staining while the wild-type Flagged-IFT140 protein predominantly localized to the basal bodies in RPE1 cells. To assess the impact of *IFT140* mutations on ciliogenesis, abundance and morphology of primary cilia were studied in cultured fibroblasts of patients and detected absent cilia in a high proportion of patient cells compared to controls. Ciliary localization of anterograde IFTs were altered in MSS patient fibroblasts supporting the pivotal role of IFT140 in proper development and function of ciliated cells.

Conclusion: Here we report on compound heterozygosity or homozygosity for *IFT140* mutations in seven MSS families. After Sensenbrenner and Jeune syndromes, MSS is the ultimate skeletal ciliopathy ascribed to IFT disorganization.

P03.40

A missense mutation in the ALDH1A3 gene cause autosomal recessive microphthalmia in a large consaguisnuos family.

R. Gershoni-Baruch[1,2], *E. Dagan*[3], *A. Mory*[2];
[1]1Institute of Human Genetics, Rambam Health Care Campus, Haifa, Israel, [2]The Ruth and Bruce Rappaport Faculty of Medicine, Technion, Haifa, Israel, [3]Faculty of Social Welfare and Health Sciences, University of Haifa, Haifa, Israel.

Here we report on large Muslim inbred kindred from Northern Israel with isolated microphthamia/anophthalmia in nine affected individuals. Assuming autosomal recessive mode of inheritance we
performed whole genome linkage analysis, on four DNA samples of affected individuals. Homozygosity mapping techniques were employed and a 1.5MB region, homozygous in all affected individuals, was delineated, further linkage analysis resulted a two point LOD score of 7.9. The region contained 9 genes, one of which; ALDH1A3, was a clear candidate gene. This gene seems to be the key enzyme in the formation of a retinoic acid gradient along the dorso-ventral axis during the early eye development and also in the development of the olfactory system. Sanger sequence analysis revealed a missense mutation, causing a substitution of Valine to Methionine at position 71. Analyzing the Val71Met mutation using Mutation Taster online predicts this variant to be disease casing (probability score:0.92). The effect of the missense mutation on the enzymatic activity was studied in vitro but results showed no changes between mutated and wiled type ALDH1A3. Recently, Lucas et al (2013), have reported on three families with anophthalmia/microphthalmia caused by mutations in ALDH1A3 gene. In summary, we report on nine affected individuals from consanguineous kindred, bearing a missense mutation in
ALDH1A3, a key enzyme in the formation of a retinoic acid gradient during the early eye development.

P03.41

Genetic analysis of insensitivity to pain in hunting dogs: a model for human sensory neuropathies

J. Plassais[1], *M. Paradis*[2], *B. Hedan*[1], *A. Pommier*[1], *E. Guaguère*[3], *l. Lagoutte*[1], *C. Hitte*[1], *C. Andre*[1];
[1]CNRS - UMR6290 - Université Rennes1 - IGDR, rennes, France, [2]University of Montreal, St-Hyacinthe, QC, Canada, [3]Clinique Vétérinaire Saint Bernard, Lomme, France.

Among different human Hereditary Sensory Autonomic Neuropathies (HSAN) and some forms of Charcot-Marie Tooth diseases (CMT), several are characterized by insensitivity to pain sometimes combined with self-mutilation. Strikingly, several purebred dogs also present similar clinical characteristics reported in the literature for fifty years. In the dog, clinical signs appear in 4 months old puppies and consist of acral analgesia, with or without sudden intense licking, biting and severe self-mutilation of the feet, whereas proprioception, motor abilities and spinal reflexes remain intact. Despite its rare occurrence in the whole dog species, several hunting dog breeds are clearly predisposed with a higher risk, i.e. estimated to 1 % in the French spaniels. Since only a few genes responsible for human homologous neuropathies have been identified, we took advantage of the dog model to search for the genetic causes of this disease in hunting dogs. To this aim, we collected blood samples from hunting breeds of which 30 are affected. Pedigree analyses allowed us to confirm a recessive inherited disease. A Genome Wide Association Study (GWAS) using the Illumina Canine HD SNP array with 24 affected and 40 healthy dogs, allowed us to identify a single 1.5Mb locus not yet described for human HSAN and CMT, with a Bonferroni corrected p-value of 2.5x10-6. We are thoroughly investigating this locus through a capture sequencing strategy since, interestingly, it contains candidate genes not yet associated to human neuropathies and thus constitutes an opportunity to identify new neuropathy genes in humans.

P03.42

Genes and mutations for olfactory phenotypes

T. Olender, *I. Keydar, A. Alkelai, E. Ben-Asher, D. Lancet;*
The Weizmann Instiute of Science, Rehovot, Israel.

Genetic variations in the Olfactory Receptor (OR) genes are likely responsible for odorant-specific sensitivity differences (anosmias),while variations in auxiliary genes, mediating neuronal transduction, development and maintenance, are candidates underlying general olfactory sensitivity (GOS) phenotypes, including congenital general anosmia (CGA). We recently generated a comprehensive account of genomic missenese variations in human ORs. We find that each individual harbors, 500-600 allelic variants with different coding sequence, a considerably higher number than locus count (413). With the reported allele-specific sensory neuronal expression, the brain receives distinct neuronal readouts of all such alleles. Further, we identified 239 segregating pseudogenes (SPGs), ORs with both intact and pseudo forms in the population. A "barcode" of missense and nonsense variants thus underlies a highly personalized smell receptor repertoire. One borderline signal, requiring validation, shows lower sensitivity to a specific odorant associated with an OR pseudogene allele. In parallel, we performed a systematic exploration for auxiliary olfactory genes and their variations. This was done using 11 data sources, including RNA-Seq of olfactory epithelium, and literature survey of olfactory-related diseases and mouse phenotypes.
One auxiliary gene variation appears to affect sensitivity to a specific odorant, suggesting a novel odorant processing mechanism. These efforts now also assist in an on-going whole exome sequencing study of 66 Jewish families with CGA, showing various modes of inheritance. The identification of specific pathogenic functional CGA variants will help elucidate the molecular basis of general olfactory sensitivity.

Association of TGFB1 with otosclerosis in a population of clinically and histologically confirmed Hungarian patients

M. Sommen[1], *G. Van Camp*[1], *B. Liktor*[2], *P. Csomor*[3], *E. Fransen*[1], *I. Sziklai*[3], *I. Schrauwen*[1], *T. Karosi*[3];
[1]University of Antwerp, Department of Medical Genetics, Edegem, Belgium, [2]Bajcsy-Zsilinszky Hospital, ENT Department, Budapest, Hungary, [3]University of Debrecen, Medical and Health Science Center, Department of Otolaryngology and Head and Neck Surgery, Debrecen, Hungary.

Otosclerosis is a frequent cause of hearing impairment in the Caucasian population characterized by abnormal resorption and deposition of the bone of the otic capsule. It is a complex disease caused by both environmental and genetic factors. Case-control association studies have implicated several genes. In order to confirm these susceptibility genes for otosclerosis, we studied a unique Hungarian otosclerosis population in which the presence of otosclerotic foci was confirmed by histological investigation. This inclusion criterium has never been used in previous association studies. We examined thirteen single nucleotide polymorphisms (SNPs) in six genes (*COL1A1*, *TGFB1*, *BMP2*, *BMP4*, *AGT* and *RELN)* in 153 otosclerosis patients and 300 unrelated controls. An association between *TGFB1* (rs1800472) and clinically and histologically confirmed otosclerosis was detected, with a similar effect size across histologically confirmed and non-confirmed otosclerosis populations. The fact that other genes did not replicate could be due to different reasons such as lack of power (*BMP2* and *BMP4*) and false positive initial association (*COL1A1* and *AGT)*. However, for *RELN,* with very reasonable power and for which association was robustly replicated in previous studies with several independent populations, this seems very unlikely. The results for *RELN* may reflect the possibility that otosclerosis is clinically heterogeneous with several endophenotypes, each with a different molecular basis.

M. Sommen: None. **G. Van Camp:** None. **B. Liktor:** None. **P. Csomor:** None. **E. Fransen:** None. **I. Sziklai:** None. **I. Schrauwen:** None. **T. Karosi:** None.

Study of allelic variants related to Quantitaive Sensory Testing parameters in patients with CRPS

M. López Bartolomé[1], *J. Fernández Mateos*[1], *M. Sánchez Barba*[2], *M. García Mellado*[3], *C. Muriel Villoria*[3], *R. González Sarmiento*[1];
[1]Unit of Molecular Medicine. Department of Medicine. University of Salamanca, Salamanca, Spain, [2]Statistic Department. University of Salamanca, Salamanca, Spain, [3]Unidad del Dolor. Hospital Universitario de Salamanca, Salamanca, Spain.

Background: Complex regional pain syndrome (CRPS) is a chronic pain condition, result of dysfunction in the central or peripheral nervous systems.

Due to the level of difficulty in the evaluation and diagnosis of neuropathic pain, a new technique, called QST (Quantitative Sensory Testing) is being used to measure changes in somatosensory function.
The aim of our study was to investigate the genetic variation of 16 genes involved in nervous system pathways, in patients from Salamanca (Spain), diagnosed CRPS, comparing these results with different parameters of the QST.
Methods: Genomic DNA was extracted from peripheral blood by standard techniques. We selected 16 non-synonymous SNPs. Studies were performed using TaqMan probes for the analysis of the polymorphisms in the following genes:. OPRM1, OPRD1, OPRK, CNR1, DRD2, GABRA, EDN1, TRPV1, NOS3 and BDNF.
Pain evaluation using VAS and QST. Statistical analysis performed with SPSS.
Results and conclusion: Preliminary analysis showed differences (p<0,05) when we compare patients and controls in OPRD1, CNR1, GABRA6 and BDNF genes. Analysis of VAS values showed significant differences in GABRA1 and EDN1 genes.
We also compared SNPs genotypic distribution with different parameters of the QST, and we found significant differences in OPRK, OPRM1 and CNR1 genes.
That support the hypothesis that polymorphism in genes involved in different pathways could be associated with increased susceptibility to develop CRPS and suffer pain. SNPs in these genes are also associated with QST parameters, reinforcing that QST could be an useful tool for the diagnose of neuropathic pain.

P03.45
A dual approach for comprehensive genetic testing of *ABCA4* in Stargardt disease

M. Bauwens[1], *C. Van Cauwenbergh*[1], *S. De Jaegere*[1], *S. Lefever*[1], *B. D'haene*[2], *F. Pattyn*[1], *B. Leroy*[3], *E. De Baere*[1], *F. Coppieters*[1];
[1]*Center for Medical Genetics Ghent, Ghent University, Ghent, Belgium,* [2]*Biogazelle, Ghent, Belgium,* [3]*Department of Ophthalmology, Ghent University Hospital, Ghent, Belgium.*

Purpose: Genetic testing of Stargardt disease, a frequent retinal dystrophy, is mostly limited to Asper chip analysis or Sanger sequencing of the coding region. To overcome its cost and limitations, we designed a comprehensive molecular test based on massively parallel sequencing (MPS) and quantitative PCR (qPCR) to identify single nucleotide and copy number variations (CNV) respectively.
Methods:
Following enrichment of the *ABCA4* coding region, pools of 12 patients were sequenced (Miseq, Illumina).
CNV screening comprised 50 qPCR assays, performed in 48 patients with one heterozygous or no *ABCA4* mutation following chip and/or sequencing, and 27 controls (LC480, Roche).
Results: Using MPS, a 20x minimal coverage was reached for 98% of the amplicons. A variant allele frequency threshold of 25% allowed detection of 99% of previously identified variants. In addition, a previously undetected indel mutation was identified in a patient with one known heterozygous mutation.
CNV analysis revealed a novel heterozygous deletion in a patient carrier of a known heterozygous splice site mutation. The deletion covers 3-4 kb, spanning exons 20-22. Breakpoint delineation is ongoing.
Conclusions: MPS for *ABCA4* proves to be a cost-efficient alternative to Sanger sequencing and chip analysis. In addition, qPCR screening identified a novel *ABCA4* deletion, being the second one reported. CNV analysis might be useful in this fraction of patients (30%) in whom only one or no coding mutation can be detected by standard approaches. Finally, the low prevalence of CNVs in unsolved Stargardt cases might point to other mechanisms such as variations in non-coding regions.

DNA Diagnostics of Retinal Stargardt Dystrophy Type 1 in Russia

M. T. Bondarenko*, A. L. Chukhrova, A. N. Loginova, A. V. Poliakov;*
Research Center for Medical Genetics, Moscow, Russian Federation.

Stargardt disease is the most common hereditary early-onset macular degeneration. Autosomal-recessive Stargardt desease type 1 (STGD1) is caused by mutations in the ATP-binding cassette transporter gene (ABCA4). ABCA4 gene mapped to 1p22, encodes 2273 amino-acid, includes 50 exons. There are about 500 mutations in the ABCA4 gene have been reported.
The two groups of unrelated control individuals and the two groups of unrelated STGD1 patients from Russia were analysed for the prevalent European ABCA4 gene mutations: G863A, G1961E, A1038V, L541P, P1380L, T1526M, P2027F, R2107H by MLPA.
In the first control group (882 individuals) the allele frequency of G863A, A1038V and G1961E were 0.17%, 0.51% and 0.62%, respectively. In the second control group (201 individuals) was found L541P only, the allele frequency - 0.25.
In the first patients group (124 individuals) the allele frequency of G863A were 1.2% and G1961E - 7.7%; in the second patients group (110 individuals) allele frequency of A1038V, L541P, P1380L were 17.7%, 18.2% and 1.8%, respectively (p<0.05). Other mutations were not found.
Heterozygous carrier frequency of G863A is high in Europe (1:18 in Northern Europe), but it is significantly lower in Russia (1:294).
L541P is detected in linking with A1038V in the compound heterozygous in 31 patients, and without A1038V in two patients only. One patient had a A1038V alone.
For the first stage STGD1 diagnosis seems comfortable to use MLPA-system to detect the five mutations, that we have found, as a full ABCA4 gene sequencing is expensive.

Fibromyalgia (FM) is a highly disabling syndrome defined by a low pain threshold and a permanent state of pain. The mechanisms explaining this complex disorder remain unclear and its genetic factors have not been identified. The aim of this study was to elucidate genetic susceptibility factors for FM.
We used the Illumina 1 million duo array to perform a genomewide association study (GWAS), and Agilent's 2X400K platform for array comparative genomic hybridization (aCGH) to identify regions varying in copy number that could be involved in FM susceptibility.
GWAS was performed in 300 FM cases and 203 controls. No SNP reached GWAS significance, but 21 of the most associated SNPs were chosen for replication in over 900 cases and 900 pain free-controls. Four of the strongest associated SNPs selected for replication showed a nominal association in the joint analysis, and one, rs11127292 (MYT1L) was found to be associated to FM with low comorbidities (p=4.28X10-5, OR (95%CI)=0.58 (0.44-0.75). By aCGH, an intronic deletion in NRXN3 showed to be associated to female cases of FM with low levels of comorbidities (p=0.021, OR (95%CI)= 1.46 (1.05-2.04)).
Both GWAS and aCGH results point at a role for the central nervous system in FM genetic susceptibility. If the proposed FM candidate genes are further validated in replication studies, this would highlight a neurocognitive involvement in this disorder, currently considered musculoskeletal and affective.
This work was partially supported by ENGAGE.

Analysis of aniridia patients by CGH-array

A. Franzoni[1], *P. Dello Russo*[1], *A. Mariutti*[2], *G. Damante*[3];
[1]Istituto Genetica medica-A.O.U. SMM, Udine, Italy, [2]Dipartimento di Scienze mediche e biologiche-Università degli Studi di Udine, Udine, Italy, [3]Istituto Genetica medica-A.O.U. SMM; Dipartimento di Scienze mediche e biologiche-Università degli Studi di Udine, Udine, Italy.

Aniridia is a rare genetic disorder due to mutation of the *PAX6* gene.
Among these mutations there are deletions, which are often not detectable through direct sequencing. Identification of deletions of the *PAX6* genomic can be performed by MLPA. However, the MLPA system does not allow a precision identification of the deletion borders. In order to set up a system for a precise identification of deletions and their borders in the *PAX6* genomic region, we used the CGH-array approach. A chip was designed in which oligonucleotides spanning a region of 20 Mb, 10 Mb in position 5' and 10 Mb in position 3', respectively to *PAX6* gene, with a probe average frequency about 500 bp. This chip was used to analyse aniridia patients with deletion of a *PAX6* genomic region previously identified by MLPA. Five individuals show deletions in a position 3' to the last exon of the *PAX6* gene. The common region of these deletions has a size of 154 Kb, and includes elements of transcriptional control of the *PAX6* gene. Our data confirm that aniridia can be due to deletion of transcriptional control elements of *PAX6* gene and demonstrate that the CGH-array approach can be successfully used to identify deletions in the *PAX6* genomic region.

Microdeletion of 6q25.1 and congenital heart defect: a case report

E. Moschella[1], *I. Loddo*[1], *M. I. S. Crapanzano*[1], *V. Salpietro*[1], *F. De Luca*[2], *M. P. Calabrò*[2], *S. Briuglia*[1];
[1]Genetics and Pediatric Immunology, Messina, Italy, [2]UOS Cardiologia Pediatrica, Messina, Italy.

We describe the case of a girl that was born to nonconsanguineous parents at 39 weeks of gestation by Cesarean section performed for perinatal suffering and intrauterine growth arrest. Birth weight was 2.240 kg. At birth was diagnosed subaortic Perimembranous Ventricular Septal Defect, so therapy with Furosemide e ACE-Inh was immediately started. She had also left renal pielectasy.
Phenotypic examination was remarkable for: flat nasal bridge, epicanthic folds, folded right helix, short neck, small hands and feet, eyelid ptosis, joint laxity, cutis laxa, generalized hypotonia, auxological parameters <3rd centile. Karyotype was normal.
At the age of 18 months she was hospitalized for failure to thrive, recurrent vomiting, food refusal and episodes of arrhythmia. Holter-ECG showed "paroxysmal supraventricular tachycardia" and then beta-blocker therapy was started.
At the age of 32 months brain MRI showed „Expansion of the cisterna magna with a wide communication with the fourth ventricle, hypoplasia of cerebellar hemispheres and vermis (Dandy Walker variant)."
Array-CGH showed a de novo microdeletion in the 6q25.1 region, extended approximately 630 kb.
In the critical region 6q25.1 was identified TAB2 gene (TAK1-binding protein 2), responsible for numerous non-syndromic congenital heart anomalies such as ASD, VSD, aortic stenosis and congenital hypoplasia of the aortic arch. In a family abnormalities in heart rhythm (paroxysmal supraventricular tachycardia) was also described in literature.
Extensive studies carried out in patients with congenital cardiac defects demonstrated the involvement of this gene in the development of cardiac structures.

New mechanisms underlying the variable phenotypes caused by N- and C-terminal SCN5A mutations

A. Ziyadeh-Isleem[1,2], *J. Clatot*[1,2,3], *S. Duchatelet*[1,2], *E. Gandjbakhch*[1,2,4], *I. Denjoy*[1,2,5], *F. Hidden-Lucet*[1,2,4], *I. Deschênes*[3], *S. Hatem*[1,2], *A. Coulombe*[1,2], *N. Neyroud*[1,2], *P. Guicheney*[1,2];
[1]Inserm U956, Hôpital Pitié-Salpêtrière, Paris, France, [2]Université Pierre et Marie Curie, Paris, France, [3]Heart and Vascular Research Center, Case Western Reserve University, Cleveland, OH, United States, [4]AP-HP, Hôpital Pitié-Salpêtrière, Département de Cardiologie. Centre de Référence pour les Maladies Cardiaques Héréditaires, Paris, France, [5]Centre de Référence pour les Maladies Cardiaques Héréditaires. Service de cardiologie, Hôpital Bichat, Paris, France.

Numerous SCN5A mutations affect the cardiac sodium channel Nav1.5 α-subunit and cause several types of arrhythmias. By expressing N- and C-terminal SCN5A mutations (R104W and R1860GfsX12) with wild-type (WT) channels in HEK cells to mimic the heterozygous state of the patients, we showed that interactions between α-subunits could modulate the channel function, location and potentially the disease phenotypes.
When expressed alone, the N- and C-terminal mutants were mostly degraded and showed either reduced or no INa density. When co-expressed with WT channels, the N-terminal mutant exerted a dominant-negative effect on WT channels by retaining them in the endoplasmic reticulum. In contrast, co-transfection of WT channels with C-terminal mutants almost restored the INa density to the level of WT and increased total and cell surface protein expression of mutant channels, suggesting that WT allow mutant proteins to escape proteasomal degradation. Co-immunoprecipitation studies showed that the WT α-subunits interacted with each other, as well as with the N- and C-terminal mutants. In addition, altered biophysical properties of INa current were found at the heterozygous state for both mutants.
In conclusion, interaction between Nav1.5 α-subunits could explain the variable phenotypes observed in SCN5A-mutation carriers. The N-terminal variant associated with a loss-of-function due to its dominant-negative effect on WT channels lead to a Brugada type-I ECG pattern. In contrast, the partial rescue of the INa current of the C-terminal variant and its altered biophysical properties could explain the complex clinical picture of sick sinus syndrome and atrial fibrillation without Brugada ECG pattern.

P04.03

Regulation of Expression of CYP19A1, MIF, ABCA1 by the Retinoic Acid Receptor-Related Orphan Receptor α (RORα)

N. Coban, *C. Gulec, B. Ozsait-Selcuk, N. Erginel-Unaltuna;*
Institute for Experimental Medical Research, Department of Genetics, Istanbul, Turkey.

The RORα is a member of the nuclear receptor superfamily of transcription factors that plays an important role in the regulation of many physiological processes. Melatonin and cholesterol are two known ligands of RORα and both were shown to be important for cardiovascular diseases like atherosclerosis. Therefore, it was suggested that RORα might play a role in the pathogenesis of atherosclerosis. In this study, we identified RORα response elements (ROREs) within the promoter regions of the CYP19A1, MIF and ABCA1 genes. ChIP analysis demonstrated RORα occupancy of the CYP19A1, MIF and ABCA1 promoters in THP-1 and HUVEC cells. Briefly, THP-1 and HUVEC cells were treated with RORα specific ligands (CPG52608 and SR1001) and after the activation of RORα, the expression of the target genes were analyzed. In the result of the analyses, we found that expression of some of target genes were differentiated in THP-1 and HUVEC cells. Furthermore, we investigated whether RORα activity in THP-1 macrophages, which play an important role in the development of atherosclerosis and express target genes of RORα, is affected by the presence of simvastatin. We observed that simvastatin repressed the expression of the studied target genes, and that this repression was partially prevented by RORα ligands (especially by SR1001). These data suggest that CYP19A1, MIF and ABCA1 are direct target genes of RORα. With the demonstration of the genes that involve in the pathogenesis of atherosclerosis might be controlled by an inducible transcription factor, this study offers a potential therapeutic treatment for the disease.

Genetic risk factors for atrial fibrillation in the Japanese population

K. Ozaki, *T. Morizono, T. Tsunoda, M. Kubo, Y. Nakamura, T. Tanaka;*
RIKEN Center for Genomic Medicine, Yokohama, Japan.

The etiology of atrial fibrillation (AF) associates on complex interactions of multiple environmental and genetic factors. We recently reported *in silico* replication study for AF susceptible chromosomal loci identified Caucasian descent by a genome wide association study (GWAS) results in a Japanese population[1)]. Here, to further validate the results of the Japanese GWAS and to identify novel AF susceptible loci, we genotyped the high-ranking single nucleotide polymorphisms in the GWAS with additional samples of approximately 1,600 cases and 17,100 controls in the Japanese. Through combination of the GWAS results, the known AF locus on chromosome 4q25, close to

PITX2, showed extremely strong association ($P < 10^{-150}$). Other three known loci, *CAV1* locus on 7q31, *ZFHX3* locus on 16q22 and *PRRX1* locus on 1q24, were also validated with statistical significance ($P < 1.0 \times 10^{-8}$). Furthermore, we identified two novel association signal on chromosome 10 and 12 ($P < 5 \times 10^{-8}$). Interestingly, the four genes (*PITX2*, *PRRX1*, *ZFHX3* and the gene on chromosome 12) encode transcription related factors with homeobox domain found in proteins related to cardiopulmonary development and/or differentiation. Stratification by age at diagnosis revealed that the greater odds ratios observed in the younger age than the older one on the three loci, *PITX2*, *CAV1*, *2* and chromosome 12. By combination of the six genetic factors, the odds ratio has risen to 4.5. These results indicate that the genetic factors significantly contribute to the etiology of AF in the Japanese.

A homozygous mutation in Smoothened, a member of the Sonic Hedgehog (SHH)-GLI pathway is involved in human syndromic atrioventricular septal defect

M. E. Baardman[1], *Y. Sribudiani*[2], *F. Verheijen*[2], *L. M. A. van Unen*[2], *R. Brouwer*[2], *M. van den Hout*[2], *C. Kockx*[2], *W. van Ijcken*[2], *T. van Essen*[1], *P. van der Zwaag*[1], *G. J. de Marchie Sarvaas*[1], *W. S. Kerstjens-Frederikse*[1], *R. M. W. Hofstra*[2];
[1]*University Medical Center Groningen, Groningen, Netherlands,* [2]*Erasmus Medical Center Rotterdam, Rotterdam, Netherlands.*

Introduction

Atrioventricular septal defect (AVSD) is a common congenital heart disease with a high impact on morbidity. It is often accompanied by other congenital anomalies and previous studies have shown that in these syndromic AVSDs defects in the SHH-GLI signaling pathway are major etiological factors. One crucial member of the SHH-GLI signaling pathway is the receptor protein smoothened. Here we present the first reported homozygous smoothened mutation in two syndromic AVSD patients.

Methods

Two probands, a twin boy and girl, presented with an AVSD, postaxial polydactyly and skin syndactyly of the second and third toes of both feet. The boy also had hypospadias. The parents were consanguineous and they had one healthy older child. Karyotyping was normal and Smith-Lemli-Opitz syndrome was excluded. Exome sequencing was performed and candidate variants were validated.

Results

A novel homozygous missense mutation p.R575W (c.1725C>T) in exon 10 of the gene *SMO* (7q32.3) was detected. Functional studies in fibroblasts of the patients showed normal expression of the SMO protein but an abnormal localization of SMO protein, outside the cilia. Moreover we show severely reduced downstream GLI1 mRNA expression after stimulation with the SHH agonist purmorphamine, These results, together with the previously described association of SHH signalling defects with AVSD and SLOS, suggest that this SMO mutation is involved in syndromic AVSD in humans.

Bicuspid aortic valve morphology in fetal Turner syndrome

K. van Engelen[1,2], *M. M. Bartelings*[3], *A. C. Gittenberger-de Groot*[3], *M. J. H. Baars*[1], *A. V. Postma*[4], *B. J. M. Mulder*[2], *M. R. M. Jongbloed*[5,6];
[1]*Dept. of Clinical Genetics, Academic Medical Center, Amsterdam, Netherlands,* [2]*Dept. of Cardiology, Academic Medical Center, Amsterdam, Netherlands,* [3]*3 Dept. of Anatomy and Embryology, Leiden University Medical Center, Leiden, Netherlands,* [4]*Heart Failure Research Center, Dept. of Anatomy and Embryology, Academic Medical Center, Amsterdam, the Netherlands., Amsterdam, Netherlands,* [5]*Dept. of Anatomy and Embryology, Leiden University Medical Center, Leiden, Netherlands,* [6]*Dept. of Cardiology, Leiden University Medical Center, Leiden, Netherlands.*

Background

Bicuspid aortic valve (BAV) is a common congenital heart defect. Animal studies demonstrated that BAVs with different leaflet orientations have distinct etiologies. BAV is particularly common in Turner syndrome (TS). As TS patients share a common genetic abnormality (monosomy X), one would expect a common morphogenetic background for BAV and thus the same BAV leaflet orientation. Indeed, 95% of BAVs in TS adults were shown to have anterior-posterior (AP) leaflet orientation. Data on BAV morphology and associated cardiovascular abnormalities in fetal TS are scarce.

Methods and results

We studied post-mortem heart specimens of 36 TS fetuses and one TS newborn. Abnormal aortic valve morphology was observed in 32 (86%): BAV in 28 (76%), unicommissural valve in 2 (5%) and atresia in 2 (5%). In BAV, the leaflets showed AP-orientation in 61% and left-right (LR) orientation in 39%. There were no significant differences in occurrence of additional cardiovascular abnormalities between hearts with AP-BAV and LR-BAV. However, *all* hearts with LR-BAV showed ascending aorta hypoplasia and tubular hypoplasia of the B-segment, as opposed to only 55% and 64% of hearts with AP-BAV, respectively.

Conclusion

The large majority of TS fetuses shows abnormal aortic valve morphology. BAVs with different leaflet orientations are present, implying that haplo-insufficiency of sex-chromosomal genes can lead to different BAV morphology types, and that additional factors have a role in determination of BAV morphology. As the proportion of LR-BAV is higher in TS fetuses than reported in adults, LR-BAV may have a worse prognosis than AP-BAV in TS.

P04.07

Phenotypic variability in generalized arterial calcification of infancy.

P. Marin Reina, *L. Marín Marzal, T. Guixeres Esteve, B. Fernandez Tudela, A. Alberola Pérez, A. Pérez Aytés;*
Hospital UyP La Fe, Valencia, Spain.

INTRODUCTION: The generalized arterial calcification of infancy (GACI) is a rare disease, with autosomal recessive inheritance. Eventhough 85% die during the first six months due to heart failure, there are wide phenotypical variability with patients with long term survival. An early treatment with diphosphonates has been used with good results. We present here two unrelated patients with different outcomes.

CASE 1: 5 weeks old newborn, premature of 33 weeks, transferred to our hospital due to heart failure and cardiorrespiratory arrest. The suspected diagnoses were viral myocharditis versus metabolopathy. The boy died four days later. The diagnosis of GACI was done by the anatomophatological study.

CASE 2: Patient born at 32 weeks of gestation with hidrops faetalis. 30 weeks of gestation had detected a pericardial effusion and hyperechogenic arterial in ultrasound. Echocardiography revealed calcifications in aorta and coronary arteries. Computed tomography and ultrasound showed extensive calcifications until the iliac arteries with low flow in renal arteries. The diagnosis of GACI was made and therapy with etidronate was started when the child was 22 days old. All calcifications disappeared when the child was 15 months and the etidronate was stopped in the second year old. Actually, patient is 6 and asymptomatic.

DISCUSSION: A high index of suspicion of these disease is needed in order to use an early treatment with biphosphonates. Also, the genetic counseling is very important for those families. There are some questions not solved like the duration of the treatment and the factors conditioning the evolution.

P04.08

Whole-exome sequencing in familial calcific aortic valve stenosis

S. Le Scouarnec[1], *C. Dina*[2], *C. Scott*[1], *M. Hurles*[1], *N. Carter*[1], *H. Le Marec*[2], *V. Probst*[2], *T. Le Tourneau*[2], *J. Schott*[2];
[1]*Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom,* [2]*INSERM UMR1087, l'institut du thorax, Nantes, France.*

Calcific aortic valve stenosis (CAVS) is a complex disease under the influence of risk factors (e.g. dyslipidemia) as well as genetic polymorphisms (e.g. in APOA). The identification of rare genetic variants with a strong effect would give major insights into the mechanisms leading the bone-like phenotype. Mutations in the NOTCH1 gene have been linked to aortic valve calcification but they only explain a handful of cases and also lead to congenital anomalies. Our aim is to uncover the first genes involved in 'degenerative' CAVS, using families that appear to be monogenic autosomal dominant forms of CAVS, including a very large pedigree of >50 cases.

First, we sequenced the exome of 20 patients affected by severe CAVS, from 9 families with ≥3 cases (mean depth: ~82X per patient). The hundreds of rare variants were prioritised according to their functional consequence and their segregation with the CAVS phenotype in the families. As a vali-

dation study, we sequenced a target of 500 kb (Agilent SureSelect capture, Illumina HiSeq sequencing) in 475 CAVS cases. The 500-kb target contained exonic regions of candidate genes from our exome sequencing project (69 genes) or the literature (31 genes), and regulatory regions. After applying standard frequency and quality filters, we performed burden tests to identify CAVS disease genes.
The identification of rare genetic variants within this project could lead to the possibility of alternative patient management for a disease that represents a major public health problem in the ageing population.

Introduction ~ Heterozygous mutations in the myosin-binding protein (MYBPC3) genes are the most frequent genetic causes of hypertrophic cardiomyopathy (HCM). Patients with MYBPC3 mutations generally have late onset disease and a relative good prognosis. Homozygous or compound heterozygous MYBPC3 mutations have been associated with early onset disease with severe hypertrophy and heart failure.
We will describe here the clinical features of a family with a homozygous mutation (p.Cys566Arg) in MYBPC3.
Case ~ The index patient (an 8 year old girl) presented with a cardiac arrest due to ventricular fibrillation at the age of 8 years. After resuscitation she underwent cardiac evaluation. The electrocardiogram (ECG) showed significant left ventricular hypertrophy (LVH) but echocardiogram and Magnetic Resonance Imaging (MRI) revealed only mild LVH. She fully recovered and underwent ICD implantation. During one year follow-up she had two appropriate ICD shocks for ventricular arrhythmias. The asymptomatic brother of the index patient (age 11 years) showed a similar typical ECG with only mild LVH on echo and MRI. Genetic testing of both the index patient and her brother showed a homozygous mutation (p.Cys566Arg) in the MYBPC3-gene. Both asymptomatic parents were heterozygous carriers of this mutation and their cardiac assessments revealed no abnormalities.
Conclusion ~ Homozygous mutations in the Myosin-Binding Protein C gene could lead to an early onset of HCM with mild hypertrophy and severe ventricular arrhythmias.

Congenital adrenal hyperplasia (CAH) is an autosomal recessive disease of steroid biosynthesis in humans. More than 90% of all CAH cases are caused by mutations of the 21-hydroxylase gene (CYP21A2), and approximately 75% of the defective CYP21A2 genes are generated through an intergenic recombination with the neighboring CYP21A1P pseudogene.
In this study, the CYP21A2 gene was genotyped in 50 patients in Tunisia with the clinical diagnosis of 21-hydroxylase deficiency. CYP21A2 mutations were identified in 87% of the alleles. The most common point mutation in our population was the pseudogene specific variant p.Q318X (26%). Three novel single nucleotide polymorphism (SNP) loci were identified in the CYP21A2 gene which seems to be specific for the Tunisian population. The overall concordance between genotype and phenotype was 98%.
With this study the molecular basis of CAH has been characterized, providing useful results for clinicians in terms of prediction of disease severity, genetic and prenatal counseling.

Objectives: Microalbuminuria (Malb) is an early marker for cardiovascular diseases and renal risk in hypertension. Several studies have identified different loci and genetic markers for the risk of developing hypertension in Malb, but the genetic basis of Malb is little known. Therefore, the objectives were the identification of genetic variations involved in the development of Malb in essential hypertension.
Methodology: we have designed an experiment which studies 1536 SNPs, selected in based results of prior GWAS, in 960 samples of hypertension Spanish population with a Custom Golden Gate Genotyping Assay of Illumina. Linear regression analysis of quantitative variables and logistic regression analysis of qualitative ones were performed using PLINK v1.07. We adjusted by age, sex, body mass index and systolic blood pressure for all analysis.
Results: we obtained an association between rs12322500(ERC1 gene) and log_UAE, 0.3253(0.1413-0.5093) and OR for Malb presence of 2.657(1.373-5.144); the AA genotype had higher value for UAE than AG/GG genotypes. Other SNP with a significant association was rs1746048(CXCL12 gene) that had for log_UAE 0.7362(0.2441-1.228), an OR for Malb presence of 28.53(3.237-251.4); the AA genotype has higher value for UAE than AG/GG genotypes. Finally, SNP rs12260555(WDFY4 gene) had log_UAE of 0.1367(0.0354-0.2381) and OR for Malb presence of 1.798(1.2-2.694); with the highest levels of UAE in the AC genotype.
Conclusions: this study shows three SNPs strongly associated with UAE and presence of Malb in hypertensive patients. These SNPs are located in genes involved in renal damaged in hypertension. Further functional studies will be necessary to confirm these results.

P04.12

Introducing a multiplex panel of markers for genetic testing of familial hypertrophic cardiomyopathy based on linkage analysis

M. Keramatipour[1], *H. Saghafi*[1], *M. Haghjoo*[2], *S. Sabbagh*[1], *N. Samiee*[2], *A. Amin*[2], *F. Vakilian*[2];
[1]*Tehran University of Medical Sciences, Department of Medical Genetics, Tehran, Islamic Republic of Iran,* [2]*Tehran University of Medical Sciences, Rajaie Cardiovascular Medical and Research Center, Tehran, Islamic Republic of Iran.*

Aims: Familial hypertrophic cardiomyopathy (HCM) is caused by mutations in genes encoding cardiac sarcomere proteins. Nowadays genetic testing of HCM plays an important role in clinical practice by contributing to the diagnosis, prognosis, and screening of high risk individuals. The aim of this study was developing a reliable testing strategy for HCM based on linkage analysis and appropriate for Iranian population.
Methods and Results: six panels of four microsatellite markers surrounding MYH7, MYBPC3, TNNT2, TNNI3, TPM1, and MYL2 genes (24 markers in total) were selected for multiplex PCR and fragment length analysis. Characteristics of markers and informativeness of the panels were evaluated in 50 unrelated Iranians. The efficacy of the strategy was verified in a family with HCM. all markers were highly polymorphic. The panels were informati-

ve in 96-100% of samples. Multipoint linkage analysis excluded the linkage between the disease and all six genes by obtaining maximum LOD score ≤ -2.

Conclusion: This study suggests a reliable genetic testing method based on linkage analysis between 6 sarcomere genes and familial HCM. It could be applied for diagnostic, predictive, or screening testing in clinical setting.

Hypertrophic Cardiomyopathy (HCM) is the most common cause of sudden death among youngsters and athletes, affecting 1:500 individuals. More than 1000 mutations are associated with this condition, especially in genes encoding sarcomere proteins.

Sudden cardiac death (SDC) is a devastating complication of several cardiovascular diseases, commonly including genetic disorders. The number of SCD in which no specific cause can be confirmed, even thorough a rigorous post-mortem examination, is still highly significant.

Recent guidelines recommend the genetic screening for family members of patients with HCM or victims of SCD.

The identification of alterations in the genes can be extremely important in the management of families, especially because it allows clarification of risk situation of asymptomatic family members and, in cases of SCD, it can provide a diagnostic.

New approaches with panels of genes, such as Sequenom MassArray System and Exome Sequencing Technology, are being developed, allowing an increase of the number of genes to be studied simultaneously and detection of a greater variety of mutations.

During the last 4 years 89 index cases were analysed in the laboratory by direct sequencing and Sequenom MassArray System.

The results of this study demonstrated that the most frequent mutated genes are the *MYBPC3* and *MYH7*, being detected in more than 50% of the analysed cases, as found in the literature.

New generation technologies promise to revolutionize the current knowledge about genetic bases of HCM and SCD and can contribute to clarify genotype-phenotype co-relation or to establish the cause of death in negative autopsies.

Mutations and Deletions mitochondrial DNA in Iranian Hypertrophic Cardiomyopathy (HCM) patients

M. Montazeri[1], *P. Baghdadi*[2], *a. mohamadian*[2], *M. Houshmand*[3];

[1]*Department of Medical Biotechnology, Faculty of Advanced Medical Science, Tabriz University of Medical Sciences, Tabriz, Iran, Tabriz, Islamic Republic of Iran,* [2]*National Institute for Genetic Engineering and Biotechnology, Tehran, Iranmani, Tehran, Islamic Republic of Iran,* [3]*National Institute for Genetic Engineering and Biotechnology, Tehran, Iran, Tehran, Islamic Republic of Iran.*

Because of the linkage between energy metabolism in the mitochondria and cardiac muscle contraction, it is reasonable to assume that mitochondrial abnormalities may be responsible for some forms of HCM. We analysed the whole mitochondrial genome in a series of 52 patients with HCM for alterations and compared the findings with those of 60 control subjects. An increased number of novel missense mutations could be detected nearly in all genes encoding for protein subunits in patients. Four mutations were found that are unpublished. The c.4384T>C in **tRNA glutamin** , c.9063A>G in **ATPase6** , c.2071 T>C, c.3170C>A, in noncoding MTRNA2 16S Also 33 polymorphisms were identified which had not been published in the MitoMap database. The c.16189T>C mutation in the D-loop region that is associated with susceptibility to DCM could be detected in 19% of patients as well as in 0% of controls. Five different deletions were found in 29 patients. Eighteen patients had 8.5 kb , Twelve 9 kb ,Seven 7.3 kb, Eight 4977 bp common deletion between nt8161-nt13640, and 11 patients had 7.4 kb deletion. Multiple deletions have been found in 21 patients.

Also 43 polymorphisms were found ,10 unpublished polymorphisms were found. A homologous amino acid A5480G, non-homologous substitutions, such as G5466A , an apparently homoplasmic substitution within tRNA genes T4384C, which affects the T_C loop of tRNA glutamine, 3 remarkable mutations (A8860G, A2706G and N3107C) most of these polymorphisms were observed .

P04.15

Identification of 22q11.2 deletion in patients from adult congenital heart disease clinic - a missed burden in the transition care

B. Chung[1], *P. Chow*[1], *A. Liu*[1], *P. Lee*[1], *V. Wong*[1], *K. Chan*[2], *M. Tang*[3], *K. Lun*[1], *E. Lau*[4], *Y. F. Cheung*[1], *K. T. Chau*[1], *Y. L. Lau*[1];

[1]*Paediatrics, Queen Mary Hospital, The University of Hong Kong, Hong Kong, Hong Kong,* [2]*Prenatal diagnosis unit, Dept of O&G, Tsan Yuk Hospital, The University of Hong Kong, Hong Kong, Hong Kong,* [3]*Prenatal diagnosis service, Dept of O&G, Tsan Yuk Hospital, The University of Hong Kong, Hong Kong, Hong Kong,* [4]*Prenatal diagnosis service, Dept of OG, Tsan Yuk Hospital, The University of Hong Kong, Hong Kong, Hong Kong.*

22q11.2 deletion syndrome (22q11DS) is a common genetic diagnosis in patients with congenital heart disease (CHD). It is multi-systemic with both congenital and later-onset features with lifelong consequences. Variable clinical expression and limited awareness contribute to its under-diagnosis. With low childhood mortality, there is an increasing number of diagnosed/undiagnosed adults, posing a hidden challenge in the transition care for patients with CHD. Our objective is to determine the prevalence of 22q11DS in adult patients with conotruncal defects and to delineate their extra-cardiac manifestations. We enrolled patients through an adult CHD clinic by active screening, using fluorescence-PCR and FISH. We have recruited 102 with conotruncal defects in 2012. Twelve patients are diagnosed with 22q11DS. Importantly 11 are not known to have 22q11Ds previously, which translates into a missed diagnosis of 1 in every 10 adults with conotruncal defects. Nine had the cardiac diagnosis of tetralogy, 2 had pulmonary atresia and ventricular septal defect, 1 had interrupted aortic arch; for extra-cardiac manifestations, 2 patients had learning difficulties, 2 had schizophrenia, 2 had history of hypocalcemia, 1 had thyroid nodule, and 1 had brain abscess. Among these 12 patients, only 1 was assessed by the cardiologists to have the typical facial dysmorphism. By cascade family testing, the deletion in 1 patient was found to be inherited from her mother with schizophrenia. The recruitment is ongoing. This study will provide important information on the disease burden of 22q11DS and may highlight an important and actionable gap in the transitional care of patients with CHD.

Congenital heart defect (CHD) occurs in 40% of Down syndrome cases. While carrying three copies of genes or other functional elements on chr21

increases the risk for CHD, trisomy 21 is not sufficient to cause CHD. Thus additional genetic variation and/or environmental factors could contribute to CHD risk. Here we use association studies to identify genomic variations that with trisomy 21, determine the risk for CHD in DS. This GWAS includes 187 DS with CHD (AVSD=69, ASD=53, VSD=65) as cases, and 151 DS without CHD as controls. Chr21 specific association study revealed rs2832616 and rs1943950 (both cis-eQTLs for KRTAP7-1) as CHD risk alleles (adjusted p-values < 0.05). These signals were confirmed in a replication cohort of 92 DS CHD cases and 75 DS controls (nominal p-value = 0.0005). Furthermore rs2183593 and rs7282991 were identified as risk factors for ASD. Since DS is likely to be a disorder of gene expression, 2-locus interaction was applied for whole genome eQTLs. A pair of interacting eQTL on chr2 and chr11 was identified. Furthermore, a search for chr21 risk CNVs for CHD was performed using a customized chr21 array of 135K probes across 55 DS-AVSD and 53 DS controls. It revealed two CNV regions (FDR=0.04) in previously defined CHD minimal region, and another CNV (FDR=0.03) upstream of POFUT2. We propose that the CHD risk of DS is complex and determined by specific SNPs and CNVs variations on chr21 and interaction of non-chr21 genomic variants.

Congenital heart defects are rarely caused by mutations in ACTC1/ACTA2 genes

T. Khodyuchenko, *A. Zlotina, D. Zverev, A. Malashicheva, A. Kostareva;*
Institute of Molecular Biology and Genetics Almazov Federal Heart, Blood and Endocrinology Centre, Saint-Petersburg, Russian Federation.

Background: It has been shown that some congenital heart defects (CHD) can have genetic background due to missens mutation in cardiomyocyte-specific genes. Thus, cardiac actin was shown to be involved in pathogenesis of CHD and smooth muscle actin in pathogenesis of aortic aneurysm in combination with patent ductus arteriosus (PDA). In present study we investigated whether mutations in human α-cardiac actin (ACTC1) and smooth muscle α-actin (ACTA2) genes can cause ASD or PDA.
Matherial and Methods: Total genomic DNA was extracted from peripheral blood of 86 patients with ASDs and 100 patients with PDA. Coding exons and flanking intron regions of ACTC1 (NM_005159.4) and ACTA2 (NM_001613) were amplified by PCR with specific primers designed according to the corresponding gene reference sequences. PCR fragments were directly sequenced using a BigDye Terminator v3.1 sequencing kit and a 3130 Genetic Analyzer (Applied Biosystems). Sequencing results were analyzed with BioEdit 7.1 software and Sequencing Analysis 5.3.1 software (Applied Biosystems).
Results: Sequence analysis of ACTA2 and ACTC1 did not identify any nucleotide changes that altered the coding sense of the genes. In the case of ACTC1 we have found the earlier described nucleotide polymorphism rs2307493 (NCBI SNP database) resulting in a synonymous substitution.
Conclusion: our results confirmed that the mutations in ACTC1 gene are rare (at least <1%) cause of ASD. In patients with PDA the mutations of ACTC 2 gene are not detected, thus, being excluded from the list of frequent PDA-associated genetic defects.

P04.18

The genetic basis of complex congenital heart disease: identification of potentially causal variants through whole-genome sequencing

S. Stenzel[1], *K. Stevens*[2], *R. Lyons*[1], *S. B. Gruber*[3], *P. J. Gruber*[4];
[1]*University of Michigan, Ann Arbor, MI, United States,* [2]*Mayo Clinic, Rochester, MN, United States,* [3]*University of Southern California, Los Angeles, CA, United States,* [4]*University of Utah, Salt Lake City, UT, United States.*

Background. Genetic risk factors contributing to the multi-factorial etiology of congenital heart disease (CHD) remain poorly understood. The goal of this study is to explore genetic variants underlying the development of complex CHD through whole-genome sequencing (WGS) of a family affected by hypoplastic left heart syndrome (HLHS) and conotruncal defects. We hypothesize that the clustering of these anatomically distinct lesions is attributable to a more proximal defect in cardiogenesis.
Methods. Paired-end, WGS data was generated on the Illumina Genome Analyzer II and Hi-Seq platforms for germline DNA from a proband with HLHS (~36X average depth of genome coverage); her affected half-sisters with tetralogy of Fallot (~38X) and truncus arteriosus (~10X), respectively; her unaffected full brother (~30X); and their shared unaffected father (~33X). Reads were aligned to the human genome reference sequence, followed by realignment and recalibration. Single nucleotide variant and short indel calls were made using the Genome Analysis Toolkit's UnifiedGenotyper. Variants with <1% minor allele frequency and all variants located in previously-published CHD-associated gene regions were identified. These variants were analyzed for co-segregation according to one of three genetic models: 1) autosomal dominant (AD) with incomplete penetrance, 2) AD with gonadal mosaicism, and 3) autosomal recessive. Variants co-segregating according to one of these models and defined as high impact and/or potentially damaging were considered causal candidates.
Results. Variant calling and co-segregation analysis identified a list of likely-damaging variants. Candidate causal variants for complex congenital heart disease will be presented.

Human valve disease is caused by copy number changes in ADAMTS19

M. Hitz[1], *J. Bigras*[2], *M. Thibeault*[2], *D. Stemple*[1], *M. Hurles*[1], *G. Andelfinger*[2];
[1]*Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom,* [2]*Sainte Justine Hospital, Montreal, QC, Canada.*

Valve defects are one of the predominant causes of cardiovascular morbidity and mortality. A third of all patients with congenital heart defects exhibit valve defects. Several structural variations have been identified in human disease including valvular heart defects. In a search for causal Copy Number Variation (CNV) we identified a family with a homozygous deletions in ADAMTS19.
We have studied a large patient discovery cohort sampled at the Sainte Justine Hospital, Montreal for disease associated CNVs and searched for small genomic imbalances resulting in homozygous deletions. After independent validation we have screened additional public cohorts for recurrent CNVs. Downstream in vivo modeling was done using antisense gene knockdown in Xenopus tropicalis oocytes.
We identified a homozygous deletion overlapping ADAMTS19 in an inbred family with two affected. The observed phenotype is a pulmonary stenosis, pulmonary artery dilatation and an aortic valve anomaly. This 475kb CNV spans the first seven exons of ADAMTS19 including part of the peptidase domain. Two additional duplications in patients with hypoplastic left heart syndrome have been observed in another cohort. Gene knockdown in Xenopus tropicalis supports a role during heart development.
This CNV is the first homozygous microdeletion observed in a family with valve disease. The importance of extracellular matrix genes in valve pathogenesis has been demonstrated in human and mouse. These findings of loss and gain of function spanning the same gene will enable a better genotype-phenotype understanding and will improve our understanding of normal and abnormal valve development.

Involvement of BAG3 and HSPB7 loci in various etiologies of systolic heart failure: results of a European collaboration assembling more than 2,000 patients

S. Garnier[1], *E. Villard*[2], *C. Hengstenberg*[3], *N. Lamblin*[4], *E. Arbustini*[5], *M. Komajda*[2], *R. Isnard*[2], *S. Cook*[6], *F. Cambien*[1], ***P. Charron***[2];
[1]*Inserm UMR937 & UPMC Univ Paris 6, Paris, France,* [2]*UPMC Univ Paris 6, Inserm UMR956, AP-HP Pitié-Salpêtrière hospital, Paris, France,* [3]*University of Regensburg, Department of Internal Medicine II, Regensburg, Germany,* [4]*Hospital Regional University of Lille - Cardiological Hospital, Lille, France,* [5]*Foundation IRCCS Polyclinic San Matteo, Center for Genetic Cardiovascular Diseases, Pavia, Italy,* [6]*Imperial College London, Heart Science Centre, London, United Kingdom.*

Background and purpose. Genetic background of multifactorial systolic heart failure (systHF) is poorly understood. However, through a recent GWAS we identified two loci associated with sporadic Dilated Cardiomyopathy (DCM): BAG3 and HSPB7 loci. We hypothesized that the two loci (1) could also be involved in systHF due to coronary artery disease (ischemic-HF) and (2) could be involved in the severity of systHF and not only in the susceptibility to develop HF.

Methods. We genotyped SNPs previously associated with DCM (rs2234962: BAG3 locus, rs10927875 and rs945417: HSPB7 locus) in 1160 European patients with ischemic-HF and 1322 controls. The severity of systHF (including left ventricle ejection fraction and LV end-diastolic diameter or LVEDD) was also analysed in ischemic-HF patients as well as in a European cohort of 1141 DCM patients.
Results. SNPs related to HSPB7 locus were significantly associated with ischemic-HF (MAF of rs10927875 and rs945417 were less frequent in patients than controls, p value 0.0017 and 0.0016 respectively) whereas SNP related to BAG3 locus was not. In patients, the two loci were not associated with severity of HF, except LVEDD that was associated with rs2234962 both in DCM patients and ischemic-HF patients (p=0.0086 and 0.012 respectively).
Conclusions. Out of the two loci previously associated with DCM we observed that HSPB7 locus was also associated with ischemic-HF whereas BAG3 locus was not, suggesting differential involvement according to the underlying cause of HF. Severity of HF was not related to the two loci, except BAG3 locus associated with LV diameter in both populations.

Introduction: CYP3A5 protein substantially increases 6β-hydroxylase activity which stimulates the sodium-retaining actions of the mineralocorticoid receptor, potentially causing high blood pressure. Most Africans are functional CYP3A5 expressers so one would expect to find a relationship between CYP3A5 and blood pressure. Our study investigates this possible explanation for the high incidence of hypertension in Africans, in a Ghanaian population.
Materials and Methods: DNA samples were obtained from 957 of a cohort of 1,013 apparently healthy individuals, who in 2001/02 had been recruited to an epidemiological study of hypertension and salt intake. They were residents of 12 villages in the Ashanti region of Ghana. The extracted DNA was, in 898 individuals, of sufficient quality to allow genotyping at the *CYP3A5*3* and *CYP3A5*6* SNPs by real-time polymerase chain reaction. Blood pressure was measured using an OMRON HEM705CP sphygmomanometer. The participants had sat for at least 5 min before three pressures were obtained one minute apart; the first reading was discarded and the mean of the second and third calculated for analysis. Hypertension was defined as systolic BP ≥140 mmHg.
Results: 244 (27.2%) of the 898 individuals were hypertensive. Although there was a possible relationship between blood pressure and degree of CYP3A5 expression, there was no statistically significant relationship between either systolic or diastolic pressure and *CYP3A5*3* or *CYP3A5*6* genotypes and their haplotypes.
Conclusion: We conclude that there is either no association between CYP3A5 expression and blood pressure or, if there is a relationship, an association that is very weak.

Brugada Syndrome (BrS) is a disorder associated with an increased risk of sudden cardiac death and specific ECG features. Loss-of-function mutations in SCN5A underlie the disorder in ~25% of patients, while other genes have been implicated but account for <1%. We here set out to identify the genetic defect underlying BrS in a 3 generation family with a case who died suddenly at 24 years old.
Individuals from the pedigree were genotyped using the Illumina-HumanOmniExpress SNP-array. Exome-sequencing was carried out in 3 individuals from the pedigree using Agilent SureSelect-Target-Enrichment 50Mb capture followed by sequencing on an Illumina-HiSeq2000. These 3 individuals were selected based on their genetic distance and the presentation of a BrS-ECG at baseline.
Linkage analysis identified a region on chromosome 8 (8p11.21-8q11.23) shared among affected family members. In parallel, comparison of 3 exomes from affected individuals and after filtering out of variants occurring at a MAF of >1% in public and in-house exome/genome databases results in 10 rare variants shared, 2 locate to chromosome 8 locus and reside in 2 different genes, namely HOOK3 and PXDNL. These 2 variants have been found at a MAF of 0.02% and 0.008%, respectively, in the NHLBI-EVP (n=6500 individuals). The function of PXDNL, which appears to be specifically expressed in heart, is yet unknown.
Combining linkage analysis and exome sequencing, we identified a chromosomal interval and a possible novel gene for BrS. Ongoing studies are aimed at investigating further the involvement of this gene in a large set of patients with BrS.

Spectrum of KLHL3 and CUL3 mutations in Familial Hyperkalemic Hypertension

H. Louis dit Picard[1], *N. Thurairajasingam*[2], *S. Latreche*[1], *S. Miserey-Lenkei*[3], *O. Pylypenko*[3], *R. Vargas-Poussou*[2], *E. Clauser*[1], *X. Jeunemaitre*[1,4,5];

Familial Hyperkalemic Hypertension (FHHt) is a rare inherited form of arterial hypertension. In 2001, two genes - WNK1 and WNK4 - were identified and subsequently found to regulate renal ion transport. In 2012, we and others identified mutations in two other genes, KLHL3 and CUL3, as responsible for the majority of cases. Kelch-like 3, is an actin-binding protein that recruit substrates for the Cullin3-based ubiquitin-ligase complex. The objective of this study was to compare inheritance and phenotype in one or the other gene.
We identified 20 different missense mutations in the KLHL3 gene in 24 FHHt index cases. The majority of them were located within conserved Kelch motifs at the surface of the molecule. There were 16 dominant, 4 de novo and 4 recessive cases and a large variability of the phenotype. Homozygous subjects had an earlier age at diagnosis (8.4 vs 35.9 years) but comparable blood pressure and biological phenotype. Analysis of the CUL3 gene revealed six de novo and 2 dominant heterozygous splice-site mutations clustered around exon 9 that lead to a loss of 57 residues corresponding to a segment linking BTB and RING-binding domains of the protein. Patients had a young age of diagnosis (10 years) and a severe clinical and biological phenotype. KLHL3 is highly expressed in the distal nephron and its inhibition by RNA interference leads to an increase of Na+-Cl- cotransporter expression at the cell membrane. All mutations should decrease the ubiquitination of this transporter and thus augment its activity in the distal nephron.

INTRODUCTION: Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited genetic vascular disorder characterized by recurrent epistaxis, cutaneous telangiectasia and visceral arteriovenous malformations (AVM) that affect many organs, including the lungs, gastrointestinal tract, liver and brain.

AIMS: To study the relationship between the phenotype and genotype in patients with a proven mutation in either ENG, ACVRL1, or less frequently MADH4.

METHOD: We used the French HHT database (CIROCO) developed for the network, which contains detailed clinical features registered from 2005 to 2013.

RESULTS: A total of 1534 HHT patients with a proved mutation were analysed. Among them, the mutated gene was ACVRL1 in 58.4%, ENG in 39.9% and MADH4 in 1.7% of patients.

The nose-bleeding event appears to be a predominant characteristic for each of the HHT populations studied: this symptom was present in 92.4, 93.4 and 88.5% of the cases of patients carrying the ENG, ACVRL1 and MADH4 mutations, respectively. Telangiectasia were present in all groups: ACVRL1 (92.7%), ENG (90.6%) or MADH4 (76%).

Patients with ENG mutations showed a higher prevalence of pulmonary arteriovenous malformations (PAVM) (72.4%) as well as a marked prevalence of cerebral arteriovenous malformations (CAVM) (24.5%). In contrast, the hepatic malformations (HAVM) manifested to be more often related to the presence of the ACVRL1 mutation (66.2%). Structurally, ENG mutations showed to be widely distributed through the gene. In contrast, ACVRL1 mutations occur preferentially in exons 3 and 7.

CONCLUSIONS: This study on a large cohort showed major differences linking the syndrome and the mutated gene.

Myocardial infarction (MI) due to coronary artery disease (CAD) is the most common cause of death in developed countries. Genetic and non-genetic factors affect risk for MI with roughly equal relative contributions. The heritability of MI has been estimated to be 0.35 and 0.38 for males and females, respectively. Known genetic risk variants explain 10 % of the additive genetic variance in susceptibility to CAD.

Despite advances in understanding the pathophysiology of MI, relatively little attention has been paid to the distinction between ST-segment elevation MI (STEMI) and non-ST-segment elevation MI (NSTEMI). This division is made based on characteristic ECG changes and the two are known to present with different baseline characteristics. It is commonly thought that STEMI results from complete occlusion of a coronary artery whereas NSTEMI is caused by partial or transient blockage. The possible differences in genetic risk factors for STEMI and NSTEMI are virtually unknown.

We performed a genome-wide association study of MI (1579 cases, 1576 controls) with stratification into NSTEMI/STEMI and replicated the results in two independent study samples. We identify a novel risk locus for MI (OR=1.28, $p=7*10^{-8}$) at 1p13.3 containing *DRAM2*, *CEPT1* and *DENND2D*. We show that the association is markedly stronger for NSTEMI (OR=1.56, $p=4*10^{-10}$) than for STEMI (OR=1.11, p=0.20). We further show that the SNPs conferring risk to NSTEMI are also associated with the expression of *DRAM2* and provide evidence suggesting that this locus contains two distinct but partially overlapping association signals.

P04.26

Compound heterozygous or homozygous truncating *MYBPC3* mutations causes severe cardiomyopathy with left ventricular noncompaction and septal defects resulting in neonatal death

J. C. Herkert[1], *Y. M. Hoedemaekers[1,2], I. M. Frohn-Mulder[2], M. Dalinghaus[2], A. van den Wijngaard[3], R. R. de Krijger[2], M. Michels[2], I. F. M. de Coo[2], M. W. Wessels[2], D. Dooijes[2,4];*
[1]University Medical Center Groningen, Groningen, Netherlands, [2]Erasmus Medical Center, Rotterdam, Netherlands, [3]Maastricht University Medical Center, Maastricht, Netherlands, [4]University Medical Center Utrecht, Utrecht, Netherlands.

Background Familial hypertrophic cardiomyopathy (HCM) is a heart muscle disease generally caused by autosomal dominant sarcomeric gene mutations leading to a phenotype in adult age. The most commonly mutated gene (20-40%) in adult-onset HCM is *myosin binding protein C* (*MYBPC3*). Idiopathic HCM in young children is rare. Our goal was to describe four neonates with severe HCM caused by compound heterozygous or homozygous truncating *MYBPC3* mutations and compare these to those described in literature.

Methods Four unrelated neonates with severe unexplained cardiomyopathy were studied. A literature review was performed to identify other patients with biallelic *MYBPC3* mutations.

Results All children presented with feeding difficulties, failure to thrive, dyspnea and died from cardiac failure before age 13 weeks. Left ventricular non-compaction was diagnosed in three patients. In the fourth, noncompaction was not a clear feature, but could not be excluded. All patients had septal defects. Two patients were compound heterozygotes for the c.2373dupG (p.Trp792fsX17) and c.2827C>T (p.Arg943X) mutation. Two were homozygous for the c.2373dupG and the c.2827C>T mutation respectively.

All reported patients with double truncating mutations in *MYBPC3* reported so far (n=21), are diagnosed with severe cardiomyopathy and/or die within the first months of life. In 52% (11/21) septal defects or a patent ductus arteriosus accompanied cardiomyopathy.

Conclusions In contrast to heterozygous mutations, homozygous or compound heterozygous truncating *MYBPC3* mutations cause severe neonatal cardiomyopathy with features of left ventricular noncompaction including septal defects in 60% of patients. Neonates with cardiomyopathy should be investigated for *MYPBC3* and other sarcomeric gene mutations.

P04.27

Analysis of single and combined genotypes of MTHFR, MTR and MTRR polymorphisms regard to content of sulfur amino acids in plasma of patients with preeclampsia and coronary heart disease

H. Akopyan, *I. Nazarko, O. Efimenko, L. Czorna;*
Institute of Hereditary Pathology of National Academy of Medical Sciences of Ukraine, Lviv, Ukraine.

Hyperhomocysteinemia is generally established etiological factor for thrombosis. We have analyzed common polymorphic variants MTHFR C677T/A1298C, MTR A2756G, MTRR A66G regard to the plasma homocysteine and cysteine level among 115 Ukrainian patients with preeclampsia and coronary artery disease (55 and 71 respectively) and 186 controls (33 pregnant and 83 non-pregnant women, and 70 men). Significant increase of homocysteine level was proved in patients with preeclampsia, whereas moderate hyperhomocysteinemia (within 15-30 mmol/L) was noted just only in 10.91% of patients with ischemic heart disease. Unexpectedly, 41.8% of such patients and less than 4% of controls showed decrease in cysteine concentrations with significant difference in mean values (239.35+47.38 and 270.93+38.28 mmol/L, P<0.05). Hypercysteinemia (>350 mmol/L) was noted in 7.27% cases in the absence of control. No significant differences in prevalence either of C677T or A1298C genotypes of MTHFR gene was established. At the same time, significantly increased proportion of MTR AA and MTRR GG genotypes were recognized as a prominent trait of patients with preeclampsia and coronary artery disease. We found 6 among 81 possible combined genotypes of MTHFR C677T and A1298C, MTR A2756G, MTRR A66G, which more than 5 times increases the risk of preeclampsia and coronary heart disease. Our data suggest a link between hyperhomocysteinemia and hypocysteinemia with carrier status of defined genotypes of methionine synthase, methionine synthase reductase and cystathionine synthase. Reducing the concentration of L-cysteine can lead to disruption of the biosynthesis of endogenous hydrogen sulphide with the loss inherent to his significant vasodilator effect.

P04.28

Genotype-phenotype discrepancies in Brugada syndrome

S. J. Van Dooren[1], *P. Brugada*[2], *D. Daneels*[1], *U. Peeters*[1], *L. Peirsman*[1], *I. Timmermans*[1], *K. Kindermans*[1], *M. Biervliet*[1], *G. Pappaert*[2], *M. Bonduelle*[1];
[1]*Centre for Medical Genetics, Vrije Universiteit Brussel - UZ Brussel, Brussels, Belgium,* [2]*Heart Rhythm Management Center, Cardiovascular Division, Vrije Universiteit Brussel - UZ Brussel, Brussels, Belgium.*

Brugada syndrome is one of common inheritable arrhythmogenic disorders in apparently structurally normal hearts, inherited as an autosomal dominant trait with incomplete penetrance and variable expression. Clinical diagnosis is based on documented ventricular arrhythmias and/or related symptoms, family history AND a type 1 spontaneous or sodium-blocker induced ST-segment ECG elevation. Genetic diagnosis is currently still based on the mutation analysis of the pore-forming α-subunit of the sodium channel gene(*SCN5A*), resulting in a genetic diagnostic yield of approximately 20%.
We performed SCN5A mutation analysis in 135 Brugada syndrome probands of our outclinic patient population. We identified 20 variants of which 17 described mutations and 3 novel potential disease causing variants by *in silico* prediction tools, resulting in a diagnostic yield of respectively 12,6% to 14,8% (3 variants included). Subsequent segregation analysis was performed in 8 large families of the identified SCN5A positive BrS probands to determine genotype-phenotype correlation. A sensitivity of 76% and specificity of 79% was assessed and could be increased up to 85% and 92% respectively with exclusion of the undescribed SCN5A variants. Revision of all ECG data revealed that some ajmaline or baseline ECG negative BrS patients with SCN5A mutations did not meet the stringent diagnostic criteria but demonstrated conduction disease.
These results urge for the need to revise the clinical diagnostic criteria for Brugada syndrome, especially since the ajmaline ECG data are of important added value for this low penetrant disorder in the discovery of novel major molecular genetic pathways in Brugada syndrome.

P04.29

Whole exome sequencing as a tool to identify novel causal variants and genes for Brugada syndrome

D. Daneels[1], *M. Bonduelle*[1], *U. Peeters*[1], *P. Brugada*[2], *G. Pappaert*[2], *S. Van Dooren*[1];
[1]*Centre for Medical Genetics, UZ Brussel & REGE, Vrije Universiteit Brussel, Brussels, Belgium, Brussels, Belgium,* [2]*Heart Rhythm Management Centre, UZ Brussel - Vrije Universiteit Brussel, Brussels, Belgium, Brussels, Belgium.*

Brugada syndrome (BrS) is a cardiac channelopathy inherited as an autosomal dominant trait with incomplete penetrance and variable expression. All published BrS-associated genes have been identified by a classical candidate gene approach, leading to a total genetic diagnostic yield of 30% (with 20% of mutations in the SCN5A gene). Currently available genomics and bioinformatics technologies allow us to identify novel and potentially major genes involved in BrS. Hence we can better address the urgent question to what extent BrS can be regarded as a pure Mendelian, monogenic disorder or as an oligo- to polygenic syndrome modulating disease expression.
We report the results of a first panel of exome sequence data of 8 stringently selected, large BrS families. Multiple candidate causal variants in genes already linked with cardiac arrhythmias and in novel cardiac genes were identified and validated with Sanger sequencing. In three families we observed that novel, in silico disease-causing variants in known cardiac arrhythmia genes did not show complete correlation with the clinical diagnosis by segregation analysis in all available family members. This phenomenon is also seen in our diagnostics lab for SCN5A mutation analysis. On one hand these results question the major causality of the analyzed variants but on the other hand they might point in the direction of a polygenic inheritance of this disorder. To further investigate this hypothesis, we currently compare exomic SNP profiles, including the type, relative burden and pattern of variants, within a cardiac arrhythmias candidate gene set between control and BrS-patient samples.

P04.30

Genetic diversity of plakophilin-2 (PKP2) and desmoglein-2 (DSG2) genes in Russian patients with arrhythmogenic right ventricular dysplasia

A. Shestak[1], *O. Blagova*[2], *V. Rumiantseva*[1], *Y. Frolova*[1], *S. Dzemeshkevich*[1], *E. Zaklyazminskaya*[1];
[1]*Russian Research Center of Surgery RAMS, Moscow, Russian Federation,* [2]*Sechenov Moscow Medical University, Moscow, Russian Federation.*

Background: Arrhythmogenic right ventricular dysplasia (ARVD) is an inherited cardiomyopathy characterized by progressive fibro-fatty replacement of the myocardium and high risk of life-threatening ventricular arrhythmias. Mutations in the genes encoding desmosomal proteins cause ARVD. Mutation rate in those genes in Russian cohort had not been studied yet.
Methods: Fifteen unrelated Russian ARVD patients were examined with collecting of personal and family history, physical examination, ECG, Echo-CG, myocardial biopsy and cardiac MRI. Analysis of PKP2 and DSG2 genes was performed by direct sequencing.
Results: Screening of mutations in PKP2 and DSG2 genes in 15 DNA samples was performed. In PKP2 gene we found three rare genetic variants: two truncating mutations (p.W538X and c.1523_1538del) and one missense VUCS p.S140F. All patients carrying 3 genetic variants had an oblivious manifestation at the 46 y.o. with high grade ventricular arrhythmia; ICD was implanted.
In DSG2 gene we did find three missense VUCSes p.S194L, p.V533I and p.N245H. Variants p.S194L and p.N245H were analysed with PolyPhen2 and considered as «probably damaging» and «possibly damaging» respectively. All patients carrying 3 genetic variants had an oblivious manifestation at the 26 y.o. with ventricular tachycardia, RV hiperthrophy; ICD implanted or strongly recommended.
Conclusion: We identified six mutations in 2 most common ARVD genes in Russian unrelated ARVD patients. Always truncated mutations and probably damaging variants account for 40% mutations. This prevalence matches with the prevalence of ARVD9 and ARVD10 (HRS/EHRA Expert Consensus Statement). Observation in healthy ethnically-matched volunteers is in progress now. Functional effect has to be elucidated.

P04.31

Ebstein anomaly: report of two siblinigs born to unaffected parents.

S. Jougheh Doust[1], *A. Redington*[2], *D. Chitayat*[1,3];
[1]*Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada,* [2]*Department of Cardiology, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada,* [3]*The Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada.*

Ebstein anomaly is a rare cardiac malformation associated with displacement of the septal leaflet of the tricuspid valve towards the apex at the right ventricle of the heart with variable severity extending from a severely affected fetus to an asymptomatic adult. Ebstein anomaly can be familial or sporadic as well as syndromic and non-syndromic. The majority of cases are sporadic and non-syndromic and the suggested mode of inheritance in familial cases is autosomal dominant (AD) (Sinokovec et al., 2005, Digilio et al., 2011) although cases suggestive of autosomal recessive mode of inheritance have been reported (Chitayat et al.,1992). A few genes including *MYH7* (Postma et al., 2010), *GATA4 and NKX2-5* (Digilio et al., 2011) have been suggested to be candidate genes in isolated, non-syndromic cases. We report two siblings (a boy and a girl) diagnosed prenatally with Ebstein anomaly and other right sided heart lesions. The parents were non-consanguineous of Swiss descents. The couple had 4 miscarriages, the 2 affected children and a healthy child. The father carries an apparently balanced chromosomal rearrangement between chromosomes 17 and 19 and array CGH done on the affected girl was negative. The Ebstein anomaly in this pregnancy seems to have autosomal recessive mode of inheritance although autosomal dominant mode of inheritance with incomplete penetrance in one of the parents cannot be ruled out. Further investigation is being done to identify the causative gene in this family.

S. Jougheh Doust: None. **A. Redington:** None. **D. Chitayat:** None.

Hypertrophic cardiomyopathy (HCM) is a common disease with an estimated prevalence of 0.2% in the general population. In 30%-60% of patients an autosomal dominant gene mutation is identified. Most of the reported mutations are distinct and unique for each family. In addition, clinical heterogeneity and incomplete penetrance are observed in families with a mutation. Occasionally, sudden cardiac death is the first manifestation of the disease.
In this report, we describe the mutation p.Glu22Lys (p.E22K, c.64G>A) in MYL2, a gene that is rarely mutated in HCM as it accounts for less than 1% of identified HCM mutations. We identified the p.E22K mutation in 11 HCM families and show that it is a Dutch founder mutation that probably originated about 425 years ago in the region around Eindhoven in the south of The Netherlands. The availability of multiple families carrying the same founder mutation provides the opportunity to investigate phenotypic differences influenced by external or genetic factors other than the primary mutation, which can improve mechanistic insights and aid in the discovery of prognostic factors. We demonstrate that mutation carriers generally have a benign disease manifestation with variable phenotype expression, reduced penetrance and late onset. However, when a comorbidity factor is present like hypertension, hypothyroidism, coronary artery disease, atrial fibrillation or a second gene mutation, disease penetrance appears to be higher with an earlier onset and sometimes cardiac arrest requiring an implantable cardioverter defibrillator in survivors.

Idiopathic pleuroparenchymal fibroelastosis: identification of two candidate loci by genome-wide homozygosity mapping in a familial case.

J. Plaisancié[1], *E. Justrabo*[2], *H. Hamel*[3], *P. Calvas*[1], *N. Chassaing*[1], *E. Bieth*[1];
[1]*Medical Genetics, Purpan Hospital, Toulouse, France,* [2]*Pathology, University Hospital, Dijon, France,* [3]*Pneumology, Bocage Hospital, Dijon, France.*

Idiopathic Pleuroparenchymal Fibroelastosis (IPF) is a rare clinicopathologic entity, characterized by a fibrotic thickening of the pleura and subpleural parenchyma with upper lobe predominance. The pathologic findings include the following: 1) intense fibrosis of the visceral pleura, 2) prominent subpleural fibroelastosis, 3) sparing of the parenchyma distant from the pleura, 4) patchy lymphoplasmatic infiltrates, 5) fibroblastic foci present at the leading edge of the fibrosis. Etiology and physiopathology of this entity are still unknown but genetic origin is suggested by reported affected sib pairs.
Here we described three sibs, a brother and two sisters, affected by a dramatic restrictive syndrome, secondary to bilateral pleural fibrosis and leading to premature death during the fourth decade. For these three sibs, clinical presentation, radiographic and pathologic findings are consistent with IPF. Their unaffected parents were first cousins and the siblings had identical symptoms with similar severe progression which is strongly indicative of a simple autosomal recessive inheritance. We identified by Genome-Wide Homozygosity Mapping two candidate loci, spanning 9,60 Mb on chromosome 5 and 8,97 Mb on chromosome 9. Unfortunately, Whole Exome sequencing strategy failed to identify the causal mutations of this rare fatal disease in our pedigree.

Mutation analysis of the *AGXT* gene in combined liver-kidney and isolated liver transplanted six children for primary hyperoxaluria type 1: a single center experience

M. Turkmen[1], *S. Agılkaya*[2], *D. Alaygut*[1], *M. Torun Bayram*[1], *B. Kasap*[1], *A. Soylu*[1], *S. Kavukcu*[1], ***S. Cingoz***[2];
[1]*Department of Pediatrics, Division of Nephrology, School of Medicine, Izmir, Turkey,* [2]*Department of Medical Biology and Genetic, School of Medicine, Izmir, Turkey.*

Primary hyperoxaluria type I (PH1) is an autosomal recessive rare disorder, characterized by progressive kidney failure, caused by mutations in the alanine: glyoxylate aminotransferase (*AGXT*) gene which leads to the failure of the alanine: glyoxylate aminotransferase activity in the liver. Although targeted sequence analysis of exons 1, 4 and 7 of *AGXT* has been proposed for first line genetic testing, the sequence of the entire coding region is recommended. We aimed to detect the *AGXT* gene mutations causing PH1 in combined liver-kidney, isolated liver, sequential kidney and liver-kidney transplanted six Turkish children (Five male) with phenotypic characteristics of PH1. Median age at diagnosis was 119 months (Range 42-178 months). The entire coding region including exon intron boundaries of the *AGXT* gene were sequenced in patients.
We detected six mutations PH1causing and two minor allele polymorphism in six patients. The entire patients had at least one PH1 related mutation. Patient 1 had homozygous minor allele polymorphisms Pro11Leu in exon 1 and Ile340Met in exon 10, and mutation Met195Arg in exon 5.
Patient 2 had homozygous mutation c. 33_34insC in exon 1. Patient 3 was compound heterozygous for mutations Gly170Arg in exon 4 and c.846+1G>A in intron 8 and heterozygous minor allele polymorphisms Ile340Met in exon 10. Patient 4 had homozygous mutation c.823-824dupAG in exon 8. Patient 5 and 6 had homozygous mutation c.976delG in exon 10. Mutational analysis of the *AGXT* gene in PH1 patients can be a useful tool for establishing the diagnosis and choosing an appropriate therapeutic strategy.

P04.35

Both genetic and allelic heterogeneity greatly influence the outcome of renal function in polycystic kidney disease patients.

E. Cornec-Le Gall, *M. P. Audrezet, J. M. Chen, Y. Le Meur, C. Ferec, T. Genkyst Working Group;*
Chru Brest, Brest, France.

Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited disorder affecting 1/400 to 1/1000 individuals worldwide. The disease is genetically heterogeneous with two causative genes, *PKD1* (85% of patients) and *PKD2* (15% of patients). To improve our understan-

ding of the genotype/phenotype correlation in ADPKD, we have collected a large population of more than 1000 patients (including The Genkyst cohort) from the western part of France. We have scanned the whole coding sequences of these two genes and searched for large rearrangements. We have identified a mutated allele in 90% of our patients and reported 351 new mutations (Audrezet et al., Human Mutation, 2012). These molecular data as well as the correlation with the patients' phenotype allowed us to show that *PKD2* mutations are associated with renal survival approximately 20 years longer than that associated with *PKD1* mutations (79.7 years versus 58.4 years). In terms of allelic effect on phenotype, in sharp contrast to previous studies, we demonstrated that it is the type but not the position of the *PKD1* mutation correlates strongly with renal survival. The median age of end stage renal disease (ESRD) onset is 55.6 years in patients with truncating mutation versus 67.9 years in the non-truncating mutation carriers (E Cornec-Le Gall, JASN, in Press).The identification of such genetic factors is crucial as targeted therapies are currently under development.

Array CGH analysis of Bulgarian patients with multiple congenital pathologies including anomalies of kidney and urinary tract

O. Beltcheva[1], *V. Penchev*[1], *A. Boueva*[2], *G. Zlatanova*[2], *G. Stancheva*[1], *T. Goranova*[1], *V. Mitev*[1], *R. Kaneva*[1];

[1]*Molecular Medicine Center, Dept. of Medical Chemistry and Biochemistry, Medical University-Sofia, Sofia, Bulgaria,* [2]*University Pediatrics Hospital, Pediatric Nephrology and Hemodialysis Clinics, Sofia, Bulgaria.*

Congenital anomalies of the kidney and urinary tract (CAKUT) represent approximately 25% of all pathologies identified in the prenatal period. These conditions constitute a broad range of disorders resulting from the abnormal renal development in embryogenesis. They are one of the most common causes of chronic renal failure in both children and adults. In the present study an array Comparative Genome Hybridization (aCGH) for 10 Bulgarian patients was performed. The children were diagnosed with different manifestations of CAKUT - unilateral agenesis, multiple cysts, VUR, hydronephrosis, etc. Many had accompanying malformations in other organs like heart, skeleton, neuronal tube, etc. All patients were initially screened for mutations in the two most commonly affected genes, TCF2 and PAX2, but no defects were identified.

Using aCGH we identified a variety of genomic rearrangements. Common copy number variations (CNV) were present in all samples. In addition, we found microdeletions and microduplications affecting multiple genes known to be expressed in kidney, which potentially have important role for urinary tract development and function - SUMF1, CROCC, TNS1, NALCN, ANXA6, ELF3, BCAR3 and SKAP2. Their protein products are implicated in cell signaling, cytoskeleton formation, transcription regulation and extracellular matrix rearrangements. To the best of our knowledge, this is the first study to identify a possible link between mutations affecting these genes and CAKUT. Further studies need to be carried out in order to confirm their involvement in the pathogenesis of these disorders.

P04.37

Mutations in TCF2 and PAX2 genes are a rare cause for Congenital Anomalies of Kidney and Urinary Tract (CAKUT) in Bulgarian patients

V. Penchev[1], *O. Beltcheva*[1], *A. Boueva*[2], *H. Rendakova*[1], *G. Zlatanova*[2], *R. Kaneva*[1], *V. Mitev*[1];

[1]*Molecular Medicine Center, Dept. of Medical Chemistry and Biochemistry, Medical University-Sofia, Sofia, Bulgaria,* [2]*University Pediatrics Hospital, Pediatric Nephrology and Hemodialysis Clinics, Sofia, Bulgaria.*

Congenital Abnormalities of Kidney and Urianry Tract (CAKUT) are common pathological conditions diagnosed in 1 out of 500 newborns worldwide. Knowledge of the fundamental causes of CAKUT is essential for understanding the mechanisms of their pathology as well as for reliable consultation, prognosis and treatment.

HNF1B (TCF2) and PAX2 are two of the important transcription factors responsible for correct kidney development. Mutations in the genes for these proteins are the most commonly identified causes for CAKUT. They are found in up to 15 % of the cases.

In the present study 40 patients from 32 families were included - 24 families of Bulgarian, 5 of Turkish and 3 of Roma origin. Each affected individual was tested for the presence of *TCF2* and *PAX2* mutations using direct sequencing of all coding regions and Multiplex Ligation-dependent Probe Amplification (MLPA). In case genetic defect was identified in the index patient we chekked the carrier status of the parents in order to determine its origin and inheritance within the family.

Genetic defects such as missense mutations and deletions of multiple exons were found in only small proportion of the cases (less than 10%). This could be explained either with the presence of as yet unknown defects in other genes involved in urinary tract development or with the different ethnic background of the patients. Including more genes in the panel for CAKUT genetic testing as well as expanding the groups of Roma and Turkish patients would allow us to clarify that.

Concentrations of calcium and sodium in the urine (UCa, UNa) are important biomarkers for various cardiovascular and renal disorders. These traits vary across individuals and part of this variance is genetically determined. Hence, we performed a genome-wide association study (GWAS) for UCa, UNa and UCa/UNa ratio in over 8,000 subjects of European descent.The discovery phase was conducted on 5,150 samples from a Swiss population based cohort (Colaus), with replication in four additional genetic isolates (CROATIA-Korcula, CROATIA-Split, INGI-Val Borbera and INGI-Carlantino) for a total of 3,122 samples. Calcium and sodium were measured in a spot urine sample and both traits, unadjusted and adjusted for urinary creatinine excretion as well as the UCa/UNa ratio were analyzed as outcome variables.

A GWAS was conducted on 2.5M single nucleotide polymorphisms (SNPs) applying a linear regression with additive model on normalized traits adjusted for age, sex and population structure. 143 SNPs with p-value below 1E-5 in 34 loci were selected for replication, and subsequently meta-analyzed. Among loci subjected to replication attempt, one locus reached the recognized genome-wide significant threshold of 1E-8 (five phenotypes), for UCa/UNa ratio. The significant signal (top SNP p-value = 1.5E-10, effect size in original scale in discovery cohort = 3.8E-3) lies within the long arm of chromosome 21 (21q22.3), in a gene-rich region. Studies are ongoing in order to determine which gene of the locus is causative for the trait variation, and the biological relevance of the association.

NEK8/NPHP9 encodes a protein that belongs to the NIMA (Never In Mitosis gene A) kinase family, which is essential for control of cell cycle progres-

sion. NEK8 is composed of a N-terminal serine/threonine kinase domain and a C-terminal RCC1 domain involved in localization of the protein at the centrosome and the base of the cilium. To date only one homozygous NEK8 mutation, located in the RCC1 domain, has been reported in a patient with early onset nephronophthisis, a frequent renal ciliopathy.
Using ciliary gene-enriched exome sequencing, we identified novel recessive NEK8 mutations in 3 cases with very severe overlapping phenotypes including renal cystic dysplasia or hypodysplasia, situs inversus, cardiopathy with hypertrophic septum and paucity of the bile ducts.
Two patients, who died early after birth, carried either compound or homozygous missense mutations. A homozygous splice mutation in intron 1, likely resulting in protein loss, was identified in a fetus who presented agenesis of the vermis, pancreatic cysts/fibrosis and abnormal genitalia in addition to multicystic kidney dysplasia and situs inversus.
We demonstrated that the NEK8 mutations affect localization of the protein at the base of the cilium. Moreover, fibroblasts of the patient carrying the two compound mutations showed defect in ciliogenesis compared to fibroblasts from control individuals.
This study extends the spectrum of ciliopathy defects associated with NEK8 mutations, from nephronophthisis to lethal developmental multisystemic disorders. Further characterization of the functional effect of the mutations and downstream affected pathways will allow to understand the pathophysiological basis if this phenotypic variability.

Background: Primary distal renal tubular acidosis (dRTA) is a rare genetic disease caused by mutations in different genes involved in the secretion of H+ ions in the intercalated cells of the collecting duct required for final excretion of fixed acids. Both autosomal dominant and recessive forms have been described; the latter is also associated with sensorineural hearing loss.
Methods: Twenty five Tunisian families were analyzed for mutations in the ATP6V1B1 and ATP6V0A4 genes by direct sequencing. Mutation dating for the founder mutations was performed by 2 methods (Kosambi formula and DMLE+2.2 program).
Results: Two founder mutations in ATP6V1B1 gene were found in 16/25 dRTA patients, one of them was estimated to be older than 2400 years. For the remaining patients, two mutations in the ATP6V0A4 gene, one of them being novel, were found in three Tunisian cases. The presence of a heterozygous missense mutation p.T30I, of the ATP6V1B1 gene, was identified in six patients; while no mutations of the second gene were detected. Any deleterious mutations of either ATP6V1B1 or ATP6V0A were found for two probands.
Conclusion: Our study gives evidence of phenotypic and genotypic heterogeneity of dRTA in Tunisian population. Five different mutations were found, two of them were due to a founder effect. Direct screening of these mutations could be a rapid and valuable tool for diagnosis of dRTA in Tunisian and North African populations.

P04.41
Founder effect of Claudin-19 p.(Gly20Asp) mutation in Spanish families with familial hypomagnesemia with hypercalciuria and nephrocalcinosis

F. Claverie-Martin, *E. Cordoba-Lanus, E. Martin-Nuñez, H. Gonzalez-Acosta;*
Hospital N. S. de Candelaria, Santa Cruz de Tenerife, Spain.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC) is an autosomal recessive tubular disorder characterized by excessive renal magnesium and calcium excretion and chronic kidney failure. This disease is caused by mutations in CLDN16 or CLDN19, encoding tight junction proteins claudin-16 and claudin-19, respectively. The identification of several FHHNC patients from Spain carrying missense mutation p.(Gly20Asp) in CLDN19 has raised the question of the origin of this mutation from a common ancestor. The aim of this study was to identify disease causing mutations among a Spanish cohort of 30 unrelated FHHNC families and to determine whether the p.(Gly20Asp) mutation is a founder mutation. The mutational analysis was carried out by sequencing the CLDN16 and CLDN19 exons and their exon-intron boundaries. Determination of the haplotypes was performed by genotyping three short tandem repeats flanking the CLDN19 locus and four single nucleotide polymorphisms located in introns 3 and 4. Our results revealed CLDN19 mutations in all the patients; no CLDN16 mutations were detected. Six different mutations were identified, four of them novel, p.(Ile41Thr), p.(Gly75Cys), p.(Gly75Ser) and p.(Gly122Arg). The p.(Gly20Asp) mutation was found in 28 unrelated patients (93.3%), and was present in homozygous state in 83.3% of the probands. Results of the haplotype analysis indicated that all alleles carrying the p.(Gly20Asp) mutation shared a common haplotype cosegregating with this mutation. These findings are consistent with the existence of a founder effect responsible for FHHNC in our cohort. Testing for the presence of this mutation should be the first genetic screening in Spanish patients.

P04.42
A rare penetrant mutation in *NEPH3* gene confers high risk of renal failure in primary hematuric glomerulopathies and of microalbuminuria in the general population

K. Voskarides[1], *M. Pieri*[1], *P. Demosthenous*[1], *K. Felekkis*[2], *C. Stefanou*[1], *M. Arsali*[3], *Y. Athanasiou*[4], *D. Xydakis*[5], *&. Stylianou*[5], *G. Goulielmos*[5], *P. Loizou*[6], *J. Savige*[7], *M. Höhne*[8], *L. A. Völker*[8], *T. Benzing*[8], *P. H. Maxwell*[9], *D. P. Gale*[9], *E. Daphnis*[5], *M. Zavros*[4], *A. Pierides*[10], *C. Deltas*[1];
[1]*University of Cyprus, Nicosia, Cyprus,* [2]*University of Nicosia, Nicosia, Cyprus,* [3]*Limassol General Hospital, Limassol, Cyprus,* [4]*Nicosia General Hospital, Nicosia, Cyprus,* [5]*University of Crete, Heraklion, Greece,* [6]*Private Clinical Laboratory, Ammochostos, Cyprus,* [7]*University of Melburne, Melburne, Australia,* [8]*University of Cologne, Cologne, Germany,* [9]*University College London, London, United Kingdom,* [10]*Hippocrateon Hospital, Nicosia, Cyprus.*

The wide spectrum of phenotypic heterogeneity, ranging from benign isolated hematuria to severe proteinuria and renal failure, is a critical issue in primary hematuric diseases, such as Thin Basement Membrane Nephropathy (TBMN) and IgA nephropathy. Phenotypic heterogeneity could be explained by the existence of modifier genes. We genotyped a cohort of well-studied adult TBMN patients (sample group 1) from 19 families, with a homogeneous genetic background, for potential functional modifier SNPs expressed in slit diaphragm (SD: pivotal to the structure of the glomerular filtration barrier). We identified six likely variants. When we categorized the patients in "Severe" and "Mild", based on the existence or not of proteinuria and renal failure, variant V353M in *NEPH3* (filtrin) gave suggestive association (genotypic association: p=0.036), where 353V is highly conserved. A pooled hematuric cohort of 524 patients (sample group 2) confirmed the association, under the dominant model (genotypic association: $p=5.0x10^{-3}$, OR=5.95 adjusting for gender/age; allelic association: $p=5.1x10^{-3}$ adjusting for patients' kinships). Genotyping 6531 subjects of the Framingham Heart Study (sample group 3) revealed an association of the homozygous 353M/M genotype with microalbuminuria in this population ($p=1.0x10^{-3}$, OR=12.8 adjusting for gender/age). Co-immunoprecipitation assays showed that 353M causes reduced Neph3 homodimerization and increased Neph3-Nephrin binding, possibly this affecting the long-term SD integrity. In conclusion, genetic association results from three independent sample groups and functional studies support a "rare variant-large effect" phenomenon for *NEPH3*-V353M in renal disease, giving also clues for common pathophysiology in hematuric diseases of glomerular origin.

Molecular diagnosis of hereditary kidney diseases: nephronophthisis, medullary cystic kidney disease, hyperuricemic nephropathies and renal cysts-diabetes syndrome

A. Aquilano[1,2], *C. Graziano*[3], *O. Baraldi*[2], *G. Comai*[2], *E. Sestigiani*[4], *E. Marasco*[1], *A. Prossomariti*[1], *P. Fici*[2], *M. Seri*[3], *A. Santoro*[4], *S. Stefoni*[2], *G. La Manna*[2], *V. Mantovani*[1];
[1]*Center for Applied Biomedical Research (CRBA), S.Orsola-Malpighi University Hospital, Bologna, Italy,* [2]*Dept. of Diagnostic Experimental and Specialty Medicine, Bologna University, Bologna, Italy,* [3]*Unit of Medical Genetics, S.Orsola-Malpighi University Hospital, Bologna, Italy,* [4]*Unit of Nephrology, Dialysis and Hypertension, S.Orsola-Malpighi University Hospital, Bologna, Italy.*

Hereditary kidney diseases (HKD) represent a heterogeneous spectrum of disorders and a leading cause of chronic renal failure. Once ultrasound and urinalysis have excluded polycystic kidney and glomerulonephritis, the family history and clinical features can help to distinguish recessive nephronophthisis from dominant nephropathies, but the differential diagnosis is still difficult due to phenotypic overlap.
Aim of this study is to develop and validate a clinical and molecular diagnostic algorithm, useful to drive the genetic screening. DNAs from 30 affected patients were submitted to direct sequencing of *NPHP5*, *UMOD*, *REN* and *HNF1B* genes. Furthermore, deletion analysis by multiplex PCR for *NPHP1* and MLPA for *HNF1B* were performed.
Six causative mutations were identified. A novel heterozygous p.E48K mutation in *REN* was found in a familial case of cystic nephropathy, hyperuricemia, hyperkalemia and anemia. The homozygous p.R489X mutation in *NPHP5* gene was detected in a patient with retinitis pigmentosa and recurrent cholangitis (Senior-Locken Syndrome). The heterozygous p.R295C variant in *HNF1B* was identified in a patient with renal failure and diabetes; this mutation is known to alter the DNA binding domain. The homozygous deletion of multiple exons in *NPHP1* gene was identified in a patient with renal medullary cysts. Heterozygous whole gene deletions of *HNF1B* were detected in a patient with medullary cysts and renal hypoplasia and in a patient with diabetes and cholestasis. Our data confirm the high genetic heterogeneity of HKD and indicate the need to broaden the genes to be screened, a goal that could be achieved thanks to NGS technology.

Nephrogenic diabetes insipidus due to a novel AVPR2 mutation. A case report.

C. Pidone*, V. Ferraù, E. Moschella, M. I. S. Crapanzano, A. Costa, R. Gallizzi, T. Arrigo, S. Briuglia, C. D. Salpietro;*
Genetics and Pediatric Immunology, Messina, Italy.

Nephrogenic diabetes insipidus (NDI) is characterized by poliuria, polydipsia, recurrent bouts of fever and acute hypernatremic dehydration after birth that may cause neurological sequelae. Prevalence is estimated at 1-2/1000000. The disease results from the failure of the renal tubules to respond to antidiuretic hormone. In most cases, the disease is X-linked recessive (90%) and caused by mutations in the gene located on Xq28, coding for the V2 receptor of antidiuretic hormone. AVPR2 is the only gene in which mutations are known to cause X-linked NDI. NDI can also be inherited in an autosomal recessive (9%) or autosomal dominant manner (1%).
We describe the case of a 12 months-old boy came to our observation for persistent fever, hypernatriemia (sodium 159 mmol/L), hyperchloremia, hyperazotemia and a family history of polyuria and polydipsia (mother, maternal aunt and maternal grandmother). At the physical examination the child showed discrete clinical conditions and febrile temperature, marked hypotonia and poor responsiveness to external stimuli, delayed motor development and failure to thrive.
After liberalization of water intake, we have seen the disappearance of fever and hypotonia, restarting of normal caloric intakes and spontaneous normalization of sodium and other electrolytes. At this point, after having achieved a normal hydration we observed polydipsia (1330 cc/die), polyuria (138 ml/Kg/die) and dilute urine (specific gravity <1.010).
Sequencing analysis of AVPR2 gene showed: c.738dupG, p.Arg247Alafs*12. The condition of heterozygous carriers of this duplication was found also in mother, aunt and grandmother: c.[738dupG];[=], p.[Arg247Alafs*12];[(=)].
The mutation that we found has never been described before.

NPHS2 mutations in steroid-resistant nephrotic syndrome: a mutation update and the associated phenotypic spectrum

K. Bouchireb[1,2,3], *O. Boyer*[1,2,3], *O. Gribouval*[2], *F. Névo*[2], *E. Huynh-Cong*[2], *V. Morinière*[4,2], *R. Campait*[4,2], *G. Mollet*[2], *C. Antignac*[4,2,3];
[1]*Néphrologie pédiatrique - Hôpital Necker - Enfants malades - MARHEA, Paris, France,* [2]*Inserm U983 - Institut Imagine, Paris, France,* [3]*Université Paris Descartes - Sorbonne Paris Cité, Paris, France,* [4]*Génétique médicale - Hôpital Necker - Enfants malades - MARHEA, Paris, France.*

Mutations in the human NPHS2 gene encoding podocin are implicated in an autosomal recessive form of non syndromic steroid-resistant nephrotic syndrome (SRNS) in both pediatric and adult patients. Patients with homozygous or compound heterozygous mutations commonly present with SRNS before the age of 6 years and rapidly progress to end-stage kidney disease with a low prevalence of recurrence after renal transplantation. Here we reviewed all the NPHS2 mutations published between 2000 and January 2013, and we also reviewed all mutations described in our personal cohort in Necker hospital. In summary we identified 5 new pathogenic mutations in addition to the 106 already described. The mutations are distributed along the entire coding region and lead to all kinds of alterations including 44 missense, 13 nonsense, 10 small insertions, 22 small deletions, 9 splicing, 2 indel mutations and 1 mutation in the stop-codon. In addition to the 101 likely pathogenic mutations, 36 variants were classified as variants of unknown significance, as these missense changes were not predicted to be deleterious by the Polyphen 2 software and/or variants that were exclusively described in the heterozygous state. Genotype-phenotype analyses established correlations between some variants and age at onset, ethnicity and clinical evolution. Based on this review, we are creating a web database using the Leiden Open Variation Database (LOVD) software that lists all identified variants and will allow the inclusion of future reports.

Bladder exstrophy and other urological defects associated with deletions in 2p14p15 involving OTX1

C. J. Jorgez[1], *J. A. Rosenfeld*[2], *V. Vangapandu*[1], *A. Sahin*[1], *S. Bian*[1], *D. Pham*[1], *C. Carvalho*[1], *J. Lupski*[1], *A. Miller*[3], *D. Weaver*[4], *B. Burton*[5], *D. Babu*[6], *J. Bamforth*[7], *D. Lamb*[1];
[1]*Baylor College of Medicine, Houston, TX, United States,* [2]*Signature Genomic Laboratories, Spokane, WA, United States,* [3]*Indiana University School of Medicine, Indianapolis, IN, United States,* [4]*indiana University School of Medicine, indianapolis, IN, United States,* [5]*Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, United States,* [6]*University of Alberta, Edmonton, AB, Canada,* [7]*university of Alberta, edmonton, AB, Canada.*

Development of the genito-urinary (GU) tract is intricate and defects include cryptorchidism (1:150), hypospadias (1:200), micropenis (1:300), vesicoureteral-reflux (VUR) (1%) and bladder-exstrophy-epispadias (BEE) (1:45000). Using array-comparative-genomic-hybridization (aCGH) we identified five individuals with deletions in the 2p14p15 region (66.0kb-5.6Mb) that include the homeodomain transcription factor orthodenticle-homolog-1 (*OTX1*). Case #1 (BEE and VUR) has the smallest deletion (66kb) encompassing only *OTX1* and was identified from 30 BEE patients using Nimblegen-3x720-aCGH and validated by Agilent-aCGH and CNV-Taqman-assays. Cases #2-5 were identified among 30,183 subjects submitted to Signature Genomics for clinical aCGH testing and had deletions validated by FISH. Cases #2-5 had *de novo* large CNVs (2.39-5.70Mb) and exhibited variable features similar to the 2p15p16.1 microdeletion syndrome including developmental delay, short stature, facial abnormalities, and GU defects. Different GU abnormalities in patients with the same gene defect are not rare. GU defects in our patients include testicular (3/5), penile (3/5), kidney (2/5), bladder (1/5), and VUR (1/5). *Otx1* null mice have prepubescent transient growth retardation and gonadal defects attributed to low levels of pituitary hormones. Two patients have short stature and three have gonadal defects. The presence of GU defects in four of our cohort and in seven of 2p15–p16.1 syndrome cases (one of them has OTX1 deleted) suggest this region encodes genes important for GU development. As conclusion, impairment of OTX1 function may lead to GU tract abnormalities as common as cryptorchirdism to as rare as BBE.

P04.47

On the origins of renal cell carcinoma, vesicoureteric reflux and C (Opitz trigonocephaly) syndrome: A complex puzzle revealed by the sequencing of an inherited t(2;3) translocation.

J. M. Darlow[1,2], *L. McKay*[3], *M. G. Dobson*[1,2], *D. E. Barton*[1], *I. Winship*[3];
[1]*National Centre for Medical Genetics, Dublin 12, Ireland,* [2]*National Children's Research Centre, both at Our Lady's Children's Hospital, Crumlin, Ireland,* [3]*University of Melbourne, Parkville, Victoria, Australia.*

The co-incidence of an inherited balanced translocation through 2q37.3 in patients who developed renal cell carcinoma (RCC) with the finding of genetic linkage in the same chromosomal band in a study of vesicoureteric reflux (VUR), an inherited developmental disorder, suggested the possibility that there might be a gene involved in urinary tract development in that band that could account for both findings. We have identified the breakpoints. On 3q, the gene *CD96* is bisected in an intron, while on 2q the break-point is in an intergenic region 103 kb from *CXCR7*. *CXCR7* expression has been reported to be elevated in > 50% of renal cell carcinomas and the gene is also involved in kidney development. This raises the possibility that the t(2;3) translocation brought an enhancer of CD96 into proximity to *CXCR7*, causing it to be misregulated, leading to a risk of RCC. Mutation of *CD96* was thought to be the cause of some cases of C Syndrome because a t(3;18) translocation was found in a case. The translocation bisected *CD96* and no gene was found at the breakpoint on chromosome 18. However, this is now shown not to be true, because none of the patients with t(2;3) have any features of C Syndrome. The other breakpoint in the C Syndrome case was in 18q12.1, which is now known to contain the desmocollin and desmoglein gene clusters, responsible for tight junction formation in epithelia, and it seems likely the mis-regulation of these genes is the true cause of the syndrome.

Renal hypodysplasia (RHD) is a heterogeneous condition encompassing a spectrum of kidney development defects responsible for pediatric end-stage renal disease and mortality. The occurrence of familial and syndromic cases indicates the existence of a genetic component.
In order to identify genes involved in recessive RHD, we analysed fetuses belonging to consanguineous families by whole exome sequencing. In two families, we identified homozygous mutations in integrin encoding genes that play a crucial role during kidney development: a missense variation in ITGA3, predicted as damaging by Polyphen2 and Sift, in a family with two fetuses with multicystic renal dysplasia and a splicing mutation in ITGA8 in two fetuses from a family with bilateral renal agenesis. These mutations were absent from SNP and in-house databases. Screening of fetuses with similar phenotypes did not allow us to identify any other ITGA3 or ITGA8 mutation.
By reexpressing the mutated ITGA3 protein in MDCK cells, we demonstrated that the L518P mutation alters epithelial morphogenesis (3D culture) and cell adhesion on laminin 5. We also showed that the ITGA8 mutation led to skipping of exon 28, resulting in a protein with in frame deletion of 33 aminoacids.
This is the first report of human mutations in ITGA3 and ITGA8 associated with RHD. However, ITGA3 mutations have been reported in association with another renal pathology, congenital nephrotic syndrome. Experiments are in progress to formally demonstrate the causative effect of these mutations in RHD and to understand the pathophysiological basis of the phenotypic variability associated with ITGA3 mutations.

Background and Aim: There is an increased mortality risk in chronic renal failure(CRF) patients taht requiring long-term haemodialysis due to the chronic inflammation. The relationship between chronic kidney failure and role of familial genetic markers remains incompletely understood. In the current study it was aimed to find out the prevalence of MEFV mutation profiles and serum amiloid A1 (SAA1) genes BcII polymorphism in CRF patients that requiring long-term haemodialysis. Method: Current cohort includes 242 CRF patients and 245 healthy individuals from the same population. Total genomic DNA was isolated from peripheral blood- EDTA and MEFV mutation analysis was carried out by reverse hybridization StripAssay and real-time techniques. The SAA1 gene was genotyped by BclI/RFLP method. Results: Various common MEFV mutations were detected in high portion of (38%) CRF patients. The most frequent mutations were E148Q and M694V respectivelly. The increased T allele frequency was detected in CRF patients when compared to the health individuals from the same population. Conclusions: The current results indicate that germ-line mutations in both genetic biomarkers (MEFV and SAA1 genes) play crucial role in CRF pathogenesis due to the long-term chronic inflammation in the current CRF cohort.

P04.50

Autosomal Recessive Steroid Resistant Nephrotic Syndrome (SRNS) in a three generation family: Expanding the genotype:phenotype correlation

G. E. Jones[1], *V. Jain*[1], *P. Vasudevan*[1], *L. Robertson*[1], *M. Pollak*[2], *J. Feehally*[3];
[1]*Leicester Clinical Genetics Department, Leicester, United Kingdom,* [2]*Department of Genetics, Harvard Medical School, Boston, MA, United States,* [3]*The John Walls Renal , University Hospitals of Leicester, Leicester, United Kingdom.*

SNRS type 2 (OMIM: 600995), is an autosomal recessive condition characterized by proteinuria, hypoalbuminemia, hyperlipidemia, and oedema. It is resistant to steroid treatment and usually progresses to end-stage renal disease before the second decade. Approximately 20-30% of cases are caused by recessive mutations in the NPHS2 gene1.
We describe a family with three generations of individuals with compound heterozygous mutations in NPHS2. Two individuals developed SNRS in childhood, while one is clinically well.
The proband was diagnosed with SRNS aged 1yr. She was referred to Genetics as her father had the same presentation, requiring kidney transplant at 10yrs. Genetic testing confirmed that both were compound heterozygotes for mutations R138Q and Q215X in the NPHS2 gene. The mother was found to be heterozygous for R138Q mutation. Cascade screening revealed that the paternal grandmother carried the Q215X, and the unaffected paternal grandfather was a compound heterozygote for R138Q and R229Q.
The R138Q mutation has been found in approximately 1/3 of familial cases, and is thought to be a founder mutation in Europe 1,2. It is associated with early onset of disease3. Q215X results in premature termination of the protein4. The R229Q is a common polymorphism with allele frequency of 3.6%, although it can lead to a late onset form in patients who are compound heterozygotes for R229Q and another mutation4.
This case is a striking example of how genetic testing is invaluable to accurately counsel a family with an autosomal recessive condition, which initially appears to be an autosomal dominant pedigree.

Urofacial syndrome (UFS) or Ochoa syndrome is a rare autosomal recessive condition characterised by voiding dysfunction of the urinary bladder with a significant risk of childhood renal failure. Most affected individuals have an abnormality of facial movement on expression which distinguishes the condition from other forms of urinary voiding dysfunction.
Previously, we reported that the majority of cases of UFS are caused by biallelic, loss-of-function mutations in *HPSE2*, which encodes heparanase 2. We present an expanded *HPSE2* mutation spectrum for previously unreported cases of UFS. Further, through exome sequencing and autozygosity mapping, we report that UFS is also caused by biallelic mutations in *LRIG2* in three unrelated families. *LRIG2* encodes the leucine-rich repeats and immunoglobulin-like domain 2 protein (LRIG2). The lack of *HPSE2* or *LRIG2* mutations in some cases of classical UFS provides evidence of further genetic heterogeneity.
The urinary tract features of UFS are indistinguishable from non-syndromic forms of voiding dysfunction. We demonstrate that novel missense variants in *LRIG2* may be associated with non-syndromic bladder dysfunction.
Little is known about the functional roles of heparanase 2 and LRIG2. However, both LRIG2 and heparanase-2 were immunodetected in nerve fascicles growing between muscle bundles within the human fetal bladder, directly implicating both molecules in neural development in the lower urinary tract.

The mutational analysis of the ACTN4 gene in patients with focal segmental glomerulosclerosis using HRM method

M. Safarikova[1], *J. Reiterova*[2], *J. Stekrova*[1], *L. Obeidova*[1], *M. Kohoutova*[1], *V. Tesar*[2];
[1]*Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University in Prague, Prague, Czech Republic,* [2]*First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Czech Republic, Prague, Czech Republic.*

Nephrotic syndrome (NS) is characterized by proteinuria, hypalbuminemia and edemas. There are four most important genes that condition the formation of hereditary nephrotic syndrome in adult patients (ACTN4, CD2AP, NPHS2 and TRPC6). The gene ACTN4, which encodes protein α-actinin 4, is responsible for the autosomal dominant form of focal segmental glomerulosclerosis (FSGS).
The mutational analysis of the gene ACTN4 was performed on the set of 48 patients with FSGS/MCD. To investigate the prevalence and possible effect of some substitutions found in FSGS/MCD patients we were also looking for these changes in 154 patients with IgA nephropathy (IgAN) and 55 patients with membranous glomerulonephritis (MGN). 200 unrelated healthy males and females without history of renal disease or abnormal urinary findings were studied as controls. High resolution melting (HRM) analysis and sequencing selected samples were used during this mutation detection.
It was found 20 exonic and intronic substitutions in the set of patients with FSGS/MCD. We found unpublished substitution 2242A>G (p.Asn748Asp) that could have causal associations with FSGS. This change was identified in 59 years old woman with FSGS and positive family history. This substitution was found neither in healthy controls nor in patients with IgAN and patients with MGN. Exon 19 seems to be a variable region due to amount of found polymorphisms. In this exon we also found unpublished substitutions c.2351C>T (p.Ala784Val), c.2378G>A (p.Cys793Tyr) and c.2393G>A (p.Gly798Asp). These changes were neither in healthy controls nor in patients with FSGS/MCD and patients with MGN.
Supported by the grant project PRVOUK- P25/LF1/2.

P04.53

Autosomal recessive hypophosphatemic rickets type 2 (ARHR2) and hypertension due to novel compound heterozygous mutations within the *ENPP1* gene

K. Kapelari[1], *B. Lorenz-Depiereux*[2], *T. Strom*[3], ***E. Steichen-Gersdorf***[1];
[1]*Department of Pediatrics, Innsbruck, Austria,* [2]*Helmholz Zentrum München, München, Germany,* [3]*Helmholz Zentrum München, Technische Universität, München, Germany.*

Hypophosphatemic rickets is a heterogeneous group of renal phosphate wasting disorders caused by elevated circulating fibroblast growth factor 23 (FGF23) which inhibits phosphate reabsorption and 1,25-dihydroxyvitamin D synthesis in the proximal renal tubules. Mutations in any of the five known genes - *PHEX* (XLH [MIM 307800]), *FGF23* (ADHR [MIM 193100]), *SLC34A3* (HHRH [MIM 241530], *DMP1* (ARHR1[MIM 241520]), and *ENPP1* (ARHR2 [MIM 613312]) causes hypophosphatemia. We report a 13 years old boy with a late onset of rickets, who presented with progressive bone deformity, genu valgus and bone pain since the age of ten years. In addition the patient had bilateral conductive hearing deficit and hypertension. Hypertension was related to hyperreninemia following stenosis of the right renal artery due to myointimal proliferation. Biochemical investigations showed an elevated alkaline phosphatase activity, decreased serum phosphate levels and an elevated FGF23 level. Autosomal dominant hypophosphatemia was excluded by sequence analysis of the *FGF23* gene. Due to the more complex phenotype of the patient we suggested sequencing of the *ENPP1* (ectonucleotide pyrophosphatase/phosphodiesterase 1) gene. Sequence analysis of *ENPP1* revealed one heterozygous non-synonymous single nucleotide variation (SNV) in exon 2 (NM_006208.2:c.275G>A, NP_006199.2:p.Gly92Asp) and one heterozygous splice site mutation in intron 21(NM_006208.2:c.2230+1G>A) of the *ENPP1* gene. Both SNVs were not found in databases of sequence variations (dbSNP137) and of mutations (HGMD), and within 1846 in house exomes. We identified two novel compound heterozygous mutations within the *ENPP1* gene in a boy with autosomal recessive hypophospatemia and a concomitant mild phenotype of generalized arterial calcification of infancy.

Mutations in a large VNTR of MUC1 are frequent in autosomal dominant medullary cystic kidney disease (MCKD)

V. Moriniere[1,2], *A. Mégarbané*[3], *S. Lebbah*[1], *A. Gnirke*[4], *B. Blumenstiel*[4], *A. Bleyer*[5], *A. Kirby*[4,6], *B. Knebelmann*[7], *C. Antignac*[8,9,2];
[1]*Reference Center MARHEA, AP-HP, Necker Hospital, Paris, France,* [2]*Department of Genetics, AP-HP, Necker Hospital, Paris, France,* [3]*Faculté de Médecine. Université Saint Joseph, Beirut, Lebanon,* [4]*Broad Institute of MIT and Harvard, Cambridge, MA, United States,* [5]*Section on Nephrology, Wake Forest School of Medecine, Winston-Salem, NC, United States,* [6]*Analytic and Translational Genetics Unit, Massachusetts Hospital, Boston, MA, United States,* [7]*Department of Adult Nephrology, AP-HP, Necker Hospital, Paris, France,* [8]*Inserm U983, Paris, France,* [9]*Université Paris Descartes, Sorbonne Paris Cité, Paris, France.*

MCKD is a rare disorder characterized by autosomal dominant tubulo-interstitial kidney disease (TIKD), sometimes associated with renal cysts and gout/hyperuricemia. UMOD mutations have been described in patients with hyperuricemia (MCKD2). Mutations in the MUC1 gene encoding mucin 1 were very recently identified in MCKD1 patients (Kirby et al, Nature Genet, 2013) using a sophisticated approach associating cloning of the genomic region, capillary sequencing and de novo assembly since next generation sequencing failed to identify them. All patients harbor a single cytosine insertion in one copy of the 60-base repeat unit of the long CG-rich coding VNTR of MUC1. The frameshift is predicted to result in a mutant protein which is expressed in the distal tubule and collecting duct of affected individuals.
Using an approach coupling PCR amplification of MwoI digestion (which selectively cleaves the reference sequence) products and primer-extension assay (SNaPshot Multiplex Kit), we tested 21 new families with clinical information for 67 patients but linkage data in only 2 families.
50 pts reached ESRD at a mean age of 46 +/-4 yrs (20-82 yrs) with high

intrafamilial variability. Early gout occurred in only 2 patients and hyperuricemia was generally absent or related to CRF. Renal cysts were present in 10/28 pts.
We detected the presence of the cytosine insertion in 11/21 families. Futhermore, we detected an additional mutation made of a 5C deletion, which is predicted to result in the same mutant protein as the cytosine deletion. These results show that MUC1 mutations represent a frequent cause of MCKD.

P04.55

Thin basement membrane nephropathy due to heterozygous *COL4A3/COL4A4* mutations is a more frequent cause of end-stage kidney disease compared to Alport syndrome

L. Papazachariou[1], *P. Demosthenous*[1], *M. Arsali*[2], *M. Zavros*[3], *A. Lazarou*[2], *M. Hadjigavriel*[4], *C. Stavrou*[5], *L. Yioukkas*[6], *K. Voskarides*[1], *A. Pierides*[7], *C. Deltas*[1];
[1]*University of Cyprus, Nicosia, Cyprus,* [2]*Limassol General Hospital, Limassol, Cyprus,* [3]*Nicosia General Hospital, Nicosia, Cyprus,* [4]*Larnaka General Hospital, Larnaka, Cyprus,* [5]*Evangelismos Hospital, Paphos, Cyprus,* [6]*Paphos General Hospital, Paphos, Cyprus,* [7]*Hippocrateon Hospital, Nicosia, Cyprus.*

Alport syndrome (AS) is a severe hereditary hematuric nephritis, associated with deafness, eye defects and early progression to end-stage kidney disease (ESKD). About 85% of all AS cases are X-linked due to *COL4A5* mutations (XLAS) and the rest are autosomal recessive due to *COL4A3/COL4A4* mutations (ARAS). Thin basement membrane nephropathy (TBMN) is the leading cause of familial microscopic hematuria (FMH) worldwide and is mostly explained by heterozygous *COL4A3/COL4A4* mutations. We recently showed that TBMN should not be considered as a benign condition, since about half of these patients progress to chronic renal failure after the age of 50 years.
We have studied, genetically and clinically, nine Greek-Cypriot AS families referred to public hospitals: four XLAS families with nine living patients (71%) and five ARAS families with four living patients (29%). *COL4A5*-P628L was found in two of the XLAS families. Only six of these living patients reached ESKD. We have also studied a large number of FMH families. We have found a heterozygous *COL4A3* or *COL4A4* mutation in 213 living patients in 27 families. Mutation *COL4A3*-G1334E was found in 16 families and it accounts for 155 patients. Of these 213 patients, 21 have reached ESKD. Interestingly, we observe that Greek-Cypriots patients with ESKD due to TBMN (21 patients) outnumber by 3.5 times those who reach ESKD due to AS (6 patients). This observation demonstrated again that TBMN is not a benign condition, as usually mentioned in the previous literature. Further investigations are needed in other populations to confirm this epidemiological finding.

Heapatitis C infected patients and liver expression of miR-122, miR-126, miR-136 and miR-181a

E. Bostjancic[1], *E. Bandelj*[1], *B. Luzar*[1], *M. Poljak*[2], *D. Glavač*[1];
[1]*University of Ljubljana, Faculty of Medicine, Institute of Pathology, Department of Molecular Genetics, Ljubljana, Slovenia,* [2]*University of Ljubljana, Faculty of Medicine, Institute of Microbiology and Immunology, Ljubljana, Slovenia.*

For hepatitis C virus (HCV) it was shown that host cellular microRNA (miRNA), *miR-122*, facilitates replication of viral RNA genome by binding to its 5'-UTR. With respect to the findings *in vitro*, the clinical impact of hepatic *miR-122* on HCV in humans is still largely unclear and little is known about the role of other host/cellular miRNAs in viral infection. We therefore analysed expression of *miR-122*, *miR-126*, *miR-181a* and *miR-136* in HCV infected patients.
Study included liver biopsies of 65 patients infected with HCV of different genotypes (gt: gt1, gt1a, gt1b, gt3 and gt4) and 9 non-infected individuals. Expression analysis of *miR-122*, *miR-126*, *miR-136* and *miR-181a* was performed by qPCR and statistically analysed for differences between gender and age of patients, genotypes, stage of fibrosis, grade of inflammation, serum level of liver enzymes, serum viral load, and presence of steatosis and mode of transmission.
Statistical analyses revealed differential expression of *miR-122*, *miR-126*, *miR-136* and *miR-181a* in HCV infected patients relative to non-infected individuals, between genotypes, and gender. Their expression was associated with the degree of fibrosis and with the grade of inflammatory activity, and correlated to the presence of steatosis of the liver, to the mode of transmission, and to the serum HCV load.
Recent advances in the relationship between HCV infection and miRNAs showed that other miRNAs may be as important as *miR-122* in the fight against HCV. Here we show, that *miR-126*, *miR-181a*, and *miR-136*, might also play a role in HCV infection.

Relationship between response to colchicine treatment and MDR1 polymorphism in FMF patients

A. Uludag[1], *C. Silan*[2], *S. Atik Yalcintepe*[1], *C. Akurut*[1], *A. Uludag*[3], *F. Silan*[1], *O. Ozdemir*[1];
[1]*Canakkale Onsekiz Mart University School of Medicine Department of Medical Genetics, Canakkale, Turkey,* [2]*Canakkale Onsekiz Mart University School of Medicine Department of Pharmacology, Canakkale, Turkey,* [3]*Canakkale Onsekiz Mart University School of Medicine Department of Family Medicine, Canakkale, Turkey.*

Familial Mediterranean Fever (FMF) is a disease, which is encountered with recurrent acute inflammatory episodes. Colchicine, which is used in FMF treatment, prevents leukocyte chemotaxis and collagen migration into the extracellular space. Multi Drug Resistance 1 (MDR1) gene codes for a significant membrane protein, and this controls xenobiotic passage-transport. We investigated the relationship between MDR1 C3435T polymorphism and colchicine response in FMF patients.
Patients were divided into three groups according their responses. Patients, who recovered from episodes with standard colchicine treatment, and had no attack in the last 1 year, were accepted as Complete Responders. Patients, whose episode number and intensity were decreased, but ongoing with the standard treatment, were accepted as "Partial Responders". Patients, whose episodes were not decreased despite the standard treatment, were accepted as "Non-responders". MDR1 C3435T genotype was defined by RT-PCR method.
MDR1 C and T allele frequencies of our FMF patients with colchicine responses of complete, partial and unresponders were C= 0.75 and T= 0.25 in complete responders; C= 0.56 and T=0.44 in partial responders; and C= 0.50 and T= 0.50 in non-responders. While T allele frequency was the lowest in complete responders to colchicine, it was the highest in the non-responders.
According to our results, Multi Drug Resistance 1 gene C3435T polymorphism acts an important role on colchicine response in FMF patients good response to colchicine treatment was related to C allele, whereas poor response was related to T allele in FMF patients.

Mechanism of MDR3 dysfunction in PFIC3 patients

T. Kim, *J. Kim, J. Choi;*
Ewha wamans univ., Seoul, Korea, Republic of.

BACKGROUND: Progressive familial intrahepatic cholestasis type 3 (PFIC3) is a rare liver disease which caused by mutation of the ATP-binding cassette, subfamily B, member 4 gene (*ABCB4*) also known as multidrug resistance 3 (*MDR3*). MDR3 is hepatocellular canalicular transporter associated with not only biliary secretion of phosphatidylcholine but also efflux of drugs and xenobiotics. This study was conducted to investigate the functional characterization of several variants of *MDR3* found in PFIC3 patients.
METHODs: Thirteen nonsynonymous *MDR3* variants found in PFIC patients were selected. Transport activity of each variant was measured through ATP-dependent uptake of paclitaxel using plasma inside-out membrane vesicles. To determine the mechanism through which *MDR3* variants change transport activity, cell surface biotinylation, immunoblotting and immunofluorescence were performed.
RESULTs: Six variants (M1, M5, M7, M8, M11 M12, M13) of *MDR3* showed a significant reduction in the transport activity, compared to the reference (p<0.05). Through cell surface biotinylation, we found that M1 and M11 showed altered protein size and the others showed decreased cell surface expression levels (p<0.05). In particular, three of them (M5, M7, M8) resulted

in decreased total protein levels in immunoblotting (p<0.05) and this result was confirmed by immunofluorescence.
CONCLUSION: Our studies revealed several *MDR3* variants result in changes in the transport activity of MDR3. Decreased transport activity of each variant can be explained by protein truncation (M1, M11), decreased total protein levels (M5, M7, M8), or impairment of membrane trafficking (M12, M13).

ABCB4 gene encodes for MDR3 protein; its mutations may impair biliary phosphatidylcholine secretion and are well-known as causes of Progressive-familial intrahepatic-cholestasis-type-3 (PFIC3) in children, but their clinical impact in adults with cholangiopathies remains ill-defined.
We consecutively evaluated 2602 subjects with hepatobiliary-disease and 90 underwent sequencing analysis of each of the 27 ABCB4 coding exons including the adjacent intronic regions; 37 had clinical diagnosis of Primary-Sclerosing-Cholangitis (PSC) of which 14 with a concomitant hepatobiliary disease (e.g, Juvenile Cholelithiasis -JC-, Intrahepatic Cholestasis of Pregnancy -ICP-), 17 had Primary-Biliary-Cirrhosis (PBC), 24 had Idiopathic-Cholestasis (IC), 1 had Autoimmune-Hepatitis and 1 had Overlap-Syndrome. Moreover, 4 subjects had experienced ICP and 6 had medical history of JC. We identified 15 different nucleotide changes that have an effect on the primary protein structure, 7 not described previously (p.E616K, p.G634E, p.G811R, p.S849YfsX24, p.L859W, p.M948I and p.Q1181X) and 8 already identified in children and adults with different cholangiopathies; the new nucleotide changes were not detected in 112 ethnically matched healthy subjects or reported as polymorphisms in dbSNP database. A single heterozygous mutation was identified in 15 and two mutations were identified in 3 subjects; among them, 6 had PSC of which 4 (4/14, ≈29%) with concomitant hepatobiliary disease, 3 (≈18%) had PBC, 4 had IC (≈17%), 2 (50%) had ICP and 3 (50%) JC. In summary, single heterozygous mutations in ABCB4 are associated to different cholangiopathies in a relevant percentage of adults, including the phenotype PSC when, in particular, JC and/or ICP are described within the clinical history.

Juvenile hemochromatosis (JH) represents a group of disorders characterised by iron overload causing liver injury, cardiomyopathy and endocrine abnormalities. Here we describe the genetic basis of JH caused by a homozygous nonsense mutation in *HJV* in a non-consanguineous family.
Hemochromatosis is generally caused by mutations in *HFE*. Recessive forms of JH are associated with mutations in *HAMP, HJV* and *TFR2*. Testing for the prevalent mutations C282Y, H63D, S65C in *HFE* revealed only the heterozygous state for H63D. No other predictably pathogenic variation was detected by *HFE* sequencing. With regard to the patient's age, *HAMP*, *HJV* and *TFR2* were analyzed. A known homozygous mutation c.196G>T, predicted to introduce premature stop codon (p.G66*), was found in *HJV*. The mutation was present only in the patient´s father who turned out to be a heterozygote. Neither MLPA nor real-time PCR revealed copy number variations in the *HJV* gene region. Fragment analysis of six STS markers indicated loss of heterozygocity (LOH) in the middle third of chromosome 1. LOH spanning the region chr1:86,020,000-162,505,000 was confirmed by genomic hybridisation on the Affymetrix Genome-wide human SNP 6.0 array. The patient´s genotypes at the overwhelming majority of the examined SNP loci outside of the LOH region were identical with those on both paternal chromosome 1 alleles.
Conclusion: JH in our patient is caused by duplication of the mutated *HJV* allele due to paternal disomy combined with 1/3 segmental isodisomy. This highlights the importance of testing clinically unrelated parents of homozygotes suffering from autosomal recessive diseases such as JH.

Viral hepatitis C infection influencing host genetic factors

L. Piekuse[1], *M. Kreile*[1], *A. Zarina*[1], *V. Sondore*[2], *J. Keiss*[2], *A. Krumina*[3];
[1]*Riga Stradins University, Scientific laboratory of molecular genetics, Riga, Latvia,* [2]*Riga East University Hospital, Infectology Center of Latvia, Riga, Latvia,* [3]*Latvian Biomedical Research and Study Center, Riga, Latvia.*

Objectives: susceptibility to viral hepatitis C and it clinical outcome could be influenced by patients mutations in detoxification enzyme coding genes and most common monogenic liver diseases.
Material and methods: 74 males and 40 females with chronic viral hepatitis C infection, age 41±13 years, 81 of them underwent antiviral treatment, 16 of them had SVR. From biochemical analysis available were level of iron, ferritin, ALT before and in time of treatment, viral load, and treatment outcome. 300 healthy individuals represented control population (195 males and 105 females) at age 21±3 years. For included individuals were tested mutations in the genes: *GSTP1* (A333G), *GSTA1* (C69T), *MTHFR* (C677T), *HFE* (C282Y, H63D), *UGT1A1* ((TA)7), *ATP7B* (H1069Q) by standard molecular methods.
Results: mutation frequencies in patient group (control group) were as follows: A333G= 0.238 (0.327, p>0.05), C69T=0.318 (0.349, p>0.05), C667T=0.297 (0.359, p>0.05), C282Y=0.053 (0.035, p>0.05), H63D=0.118 (0.121, p>0.05), (TA)7=0.384 (0.35, p>0.05), H1069Q=0.048 (0.013, OR=3.77, p=0.05). With biochemical markers association was found for ferritin with alleles (TA)7 (DOMDEV model, r^2=-289.1, p=0.005) and C282Y (ADD model, r^2=499.3, p=0.02), for ALT before treatment with allele A333G (ADD model, r^2=-36.33, p=0.027), for ALT in treatment with alleles C677T (ADD model, r^2=-23.62, p=0.05) and C282Y (ADD model, r^2=67.21, p=0.03), viral load before treatment with - C677T (ADD model, r^2=0.9, p=0.036).
Conclusions: (TA)7, C282Y, A333G and C677T alleles has impact on inflammation severity in liver during hepatitis C viral infection. C282Y and H1069Q alleles could be influencing susceptibility to hepatitis C virus.

P04.62
Identification of rare variants in patients with isolated biliary atresia by exome sequencing.

E. A. Tsai[1], *C. M. Growchowski*[2], *L. D. Leonard*[2], *K. M. Loomes*[2], *B. A. Haber*[3], *N. B. Spinner*[2], ***M. Devoto***[2];
[1]*University of Pennsylvania, Philadelphia, PA, United States,* [2]*The Children's Hospital of Philadelphia, Philadelphia, PA, United States,* [3]*Merck Research Laboratories, North Wales, PA, United States.*

Biliary atresia (BA) is a severe pediatric liver disease resulting in necro-inflammatory obliteration of the extrahepatic biliary tree and presenting within the first few months of life. The etiology of BA is unknown, with evidence for infectious, environmental, and genetic factors described. Possible genetic risk factors include a BA associated locus flanked by *XPNPEP1* and *ADD3* revealed by GWAS, a report of *JAG1* missense mutations in a small percentage of patients, and a BA-associated deletion on 2q37.3 revealed by CNV analysis. Animal models have suggested candidate genes, but mutations have not been found in humans until now. We performed exome-sequencing on 30 Caucasian, non-syndromic BA patients to further investigate the genetic basis of BA. Exomes were captured using Agilent All Exon V5 71MB kit and sequenced with the Illumina HiSeq platform. The 100bp paired-end reads were aligned to GrCH37 using BWA and processed using Picard and SAMtools. Variants were called using GenomeAnalysis ToolKit. There were

a total of 4,938 loss-of-function or non-synonymous variants in these samples. We filtered across the 1000 Genomes Phase I data and NHBLI Exome Sequencing Project datasets to investigate variants that occur in less than 1% of these populations. We found one likely damaging variant in both *ZEB2* and *ZIC3*, genes previously reported in patients with BA findings. We also found five likely damaging variants across several candidate genes such as *ADD3* and those implicated by animal models of BA. Our results suggest that genetic susceptibility to BA is likely to be highly heterogeneous.

Potential role of ISV-8 poly-T variants of CFTR gene in recurrent idiopathic pancreatitis: A case series of four children

I. Loddo[1], *C. Liuzzo*[1], *V. Procopio*[1], *M. Priolo*[2], *C. Mammì*[2], *S. Cardile*[1], *S. Briuglia*[1], *C. Romano*[1], *C. Laganà*[2], *C. Salpietro*[1];
[1]*UOC Genetics and Pediatric Immunology, University of Messina, Messina, Italy,* [2]*UOC Medical Genetics, AO „Bianchi-Melacrino-Morelli", Reggio Calabria, Italy.*

Background: The 5T variant is a stretch of five contiguous thymidines at the 3' of the intron 8 of CFTR gene that exacerbates skipping of exon 9, resulting in reduced levels of functional CFTR protein. This process seems to be influenced by the number of TG repeats immediately adjacent to 5T. Individuals carring 5T adjacent to either 12 or 13TG repeats are more likely to exhibit an abnormal phenotype (non-classic cystic fibrosis, recurrent pancreatitis) than those with 5T adjacent to <12TG.
Materials and methods: We describe the cases of 4 children (aged 12, 10, 6 and 3 years) affected by recurrent idiopathic pancreatitis. The diagnosis of pancreatitis was made by the presence of typical abdominal pain, serum amylase and/or lipase 3 times greater than the upper limit of normal and characteristic imaging findings. Sequence analysis of PRSS1, SPINK1 and CFTR genes was performed.
Results: Sequence analysis showed the absence of mutations in PRSS1 and SPINK1 genes.
CFTR gene sequencing in three boys showed the presence of following polymorphisms: 5T/5T-12TG/12TG; 5T/5T-11TG/12TG; 5T/9T-13TG/11TG.
The 3-years old girl with the most severe form of idiopathic pancreatitis showed 5T/7T-13TG/9TG. The 5T allele, in *cis* with 13TG, was associated in *trans* with F508del, a severe CFTR mutation.
Conclusions: The high prevalence of 5T carriers makes the assessment of the TG repeat number of great interest as a reliable predictor of the 5T penetrance. Further studies comparing the prevalence of the 5T-poly(TG) haplotypes to the general population are needed to define their role in pancreatic disease.

P04.64

Novel IL-10RA splice-site mutation causes autosomal recessive inflammatory bowel disease

B. Yerushalmi[1], ***M. Feinstein***[2], *O. S. Birk*[3,2];
[1]*Division of pediatrics Soroka university medical center, Beer-sheva, Israel,* [2]*Morris Kahn laboratory of human genetics at the National Institute of Biotechnology in the Negev, Beer-sheva, Israel,* [3]*Morris Kahn Laboratory of Human Genetics at the National Institute of Biotechnology in the Negev, Beer-sheva, Israel.*

Ulcerative colitis and Crohn's disease are chronic inflammatory bowel diseases (IBDs), rarely expressed in an early onset form (EO-IBDs). These early onset forms are characterized by a particularly severe and predominantly pancolitic inflammation, and have been shown to be caused by mutations in IL10RB (IBD25 , MIM123889) and IL-10RA (IBD28 , MIM146933). Eight individuals of a large Bedouin kindred in southern Israel presented with an autosomal recessive phenotype of EO-IBD. Homozygosity of affected individuals and heterozygosity of obligatory carriers was assayed at the IBD25 and IBD28 loci: while there was no association with IBD25, polymorphic markers at the IBD28 locus demonstrated full segregation with the disease phenotype. Sequencing of IL10RA revealed a novel homozygous point mutation. IL-10 is an anti-inflammatory cytokine secreted by a variety of cell types and is critical for maintaining immune homeostasis in the gastrointestinal tract. The mutation is synonymous, but as it is located at the first nucleotide of a conserved splice donor site, it is essential for splice-site recognition. Sequencing of an affected individual's cDNA revealed that destruction of the natural splice site led to the absence of 18 nucleotides of the coding region of IL-10RA, eliminating 6 amino acids. The mutation was not found in the 1000 Genomes Project, NHLBI Exome Sequencing Project or in any of 200 control chromosomes of Bedouin controls.

Intractable diarrhea of infancy syndrome (IDIS) is a non-infectious diarrhea lasting more than 2 weeks. Onset is observed within the first few weeks of life leading to malabsorption and failure to thrive, and is associated with great suffering and high mortality. We have encountered 6 IDIS patients from different families of Iraqi jewish origin. SNP analysis together with Exome sequencing detected two different deletion alleles, ΔS and ΔL. Performing long range PCR we established the exact boundaries for the two deletions, which share 1476bp, on the short arm of chromosome 16 (16p13.3).
Using multiplex PCR assays, we determined the form in which these deletions appear in all 6 patients . Full segregation was found among the Iraqi patients with autosomal recessive patterns of inheritance, while the deletions were not found in 200 controls. The shared 1476bp deletion does not encompass any known genes; however, it does include a predicted enhancer. It is possible that the enhancer's target is a transcription factor controlling a developmental event crucial for normal gastrointestinal function. To test this hypothesis, we assessed for the expression of the 1476bp region in a transgenic mouse model and observed reproducible enhancer activity in the stomach, duodenum and pancreas of mouse embryos at days 11.5, 12.5, and 13 not later and neither in grown mice. To further study these deletions we amplified candidate genes around the deletion, but so far we have not observed any differences between patient and control cDNAs.

Toward the genetic basis of oesophageal atresia: clinical and molecular study by next generation sequencing

E. Andreucci[1], *S. Romano*[1], *A. Provenzano*[2], *B. Mazzinghi*[1], *M. Pantaleo*[1], *L. Giunti*[1], *E. Lapi*[1], *S. Bargiacchi*[2], *O. Zuffardi*[3], *S. Giglio*[1,2];
[1]*Medical Genetics Unit, Meyer Children's Hospital, University of Florence, Florence, Italy,* [2]*Medical Genetics Section, Department of Biomedical Experimental and Clinical Sciences, University of Florence, Florence, Italy,* [3]*Medical Genetics, University of Pavia, Pavia, Italy.*

Oesophageal Atresia (OA) consists in the interruption of the continuity of the oesophagus sometimes associated with a persistent communication with the trachea (tracheo-oesophageal fistula). Its incidence is 1 in 3500 births, with associated anomalies - cardiac malformations being the most common - present in around half of the cases (syndromic OA). It's aetiology is still unknown: twin and family studies have suggested that genetic factors don't play a major role; however, at least 3 genes are involved in the etiology of syndromic OA: NMYC in Feingold syndrome, SOX2 in anophthalmia-esophageal-genital syndrome and CHD7 in CHARGE association. Moreover, microdeletions of the FOX gene cluster (FOXF1, MTHFSD, FOXC2, FOXL1) were reported to cause a phenotype resembling VACTERL association.
We studied a cohort of 10 subjects with OA, firstly excluding genomic imbalances by array-CGH analysis and later analysing 9 genes, potentially involved in the disorder, by next generation sequencing. Selected genes were those reported as associated with syndromic forms of OA, and those described in literature as potentially causative. We found 50% of cases with predicted damaging variants, among which two in DST, encoding a protein component of desmosomes that anchors intermediate filaments to desmosomal plaques; and two in DSP, encoding a protein member of the plakin protein family of adhesion junction plaque proteins. These mutations were not present in dbSNPs135 nor in the Exome Sequencing Project. Our initial results suggest that, even in a multifactorial condition, high-throughput sequencing

can identify genes that could allow to better understand the pathogenesis of the disease.

Recurrence of Hirschsprung disease due to maternal mosaicism of a novel *RET* gene mutation

*C. Amiñoso[1,2], **S. Garcia-Minaur**[1,2], J. Tenorio[1,2], L. Martinez[3], J. Tovar[3], P. Lapunzina[1,2], J. Solera[1,2];*
[1]Institute of Medical and Molecular Genetics, Hospital Universitario La Paz, Madrid, Spain, [2]Unit 753, Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Instituto de Salud Carlos III, Madrid, Spain, [3]Pediatric Surgery Department, INGEMM and IdiPAZ Research Laboratory. Hospital Universitario La Paz, Universidad Autónoma de Madrid, Madrid, Spain.

Hirschsprung disease (HSCR, MIM 142623) or aganglionic megacolon is the most frequent genetic cause of congenital intestinal obstruction. Several genes have been implicated in isolated HSCR. Inactivating mutations of *RET*, transmitted in an autosomal dominant fashion with incomplete and sex-dependent penetrance, are identified in about 50% of familial cases.We report a family with recurrence of long-segment HSCR in two siblings. Mutation analysis of *RET* performed by PCR and direct sequencing identified a heterozygous truncating mutation in both
siblings. The same mutation was identified in the unaffected mother but the electropherographic signal intensity of the mutant allele was low, suggesting a mosaic mutation. The same result was obtained when the analysis was carried out in genomic DNA from buccal cells.We are not aware of any other cases of somatic mosaicism for *RET* mutations reported in isolated HSCR familial cases. As the somatic mosaic mutation in the mother was detected by a widely used standard method (direct sequencing), we wonder whether this is a truly unique family or whether the true frequency of somatic and germ-line mosaicism is underestimated in HSCR. Based on these findings we would recommend that germ-line or somatic mosaicism should be specifically looked for in families with recurrence of HSCR in the offspring of unaffected parents.

P04.68

Dense genotyping of immune-related disease regions identifies nine new risk loci for primary sclerosing cholangitis

***J. Z. Liu**[1], J. Roksund Hov[2,3], T. Folseraas[2,3], E. Ellinghaus[4], A. Franke[4], C. A. Anderson[1], T. H. Karlsen[2,3];*
[1]Wellcome Trust Sanger Institute, Hinxton, United Kingdom, [2]Oslo University Hospital, Oslo, Norway, [3]University of Oslo, Oslo, Norway, [4]Christian-Albrechts-University of Kiel, Kiel, Germany.

Primary sclerosing cholangitis (PSC) is a severe liver disease of unknown etiology leading to fibrotic destruction of the bile ducts and ultimately the need for liver transplantation. We compared 3,789 European ancestry PSC cases to 25,079 population controls across 130,422 single-nucleotide polymorphisms (SNPs) genotyped using Immunochip. We identified 12 genome-wide significant associations outside the human leukocyte antigen (HLA) complex, nine of which were novel, thereby increasing the number of known PSC risk loci to 16. Despite comorbidity with inflammatory bowel disease (IBD) in 72% of the patients, six of the 12 loci showed significantly stronger association with PSC than IBD, suggesting an overlapping yet distinct genetic architecture. We incorporated pleiotropy with seven diseases clinically co-occurring with PSC and found suggestive evidence for 33 additional PSC risk loci. These findings further complete the genetic risk map of PSC and considerably expand on the relationship between PSC and other immune-mediated diseases.

Telomerase gene copy number is increased in IBD and PSC

***A. Amiel**[1,2], Y. Sulayev[2], H. Katz[2], A. Stein[3], M. Liberman[4], F. Konikoff[3], I. Laish[3];*
[1]Genetic Institute, Kfar Saba, Israel, [2]Faculty of Life Science, Bar-Ilan University, Ramat Gan, Israel, [3]Gastroenterology and Liver Institute, Meir medical center, Kfar Saba, Israel, [4]Genetic Institute, Meir medical center, Kfar Saba, Israel.

Background: Telomerase is an enzyme complex that lengthens telomeres. It is composed of the catalytic subunit of human telomerase reverse transcriptase (hTERT) and the telomerase RNA component (TERC) encoded by TERC gene. Gene amplifications involving the TERC gene (3q26) are frequent in human tumors. Primary sclerosing cholangitis (PSC) and Inflammatory bowel disease (IBD) are two pre-malignant conditions. The aim of this study was to evaluate the TERC gene copy number and senescence status in peripheral lymphocytes of patients with PSC and IBD, as a possible surrogate marker for increased tendency for malignancy.
Methods: By applying fluorescence in situ hybridization (FISH) to leukocytes of 14 PSC patients, 13 IBD patients (8 with Crohn's disease, 5 with Ulcerative colitis) and 12 healthy controls, we estimated gene dosage of the TERC gene at 3q26.3. The cells in senescence were evaluated from the nuclei fragmentation on the DAPI staining.
Results: The percentage of cells with more than two copies of TERC gene was significantly higher in PSC patients [mean (3 x red signals) 44.7] than in IBD patients [mean 29.6] and controls [mean 3.86] (p value < 0.0001). The TERC gene copy number was also higher in PSC patients with concomitant colitis (64%) despite significantly lower disease activity indices. Significantly more cells in senescence status were also observed in the PSC group.
Conclusion: TERC gene copy number and senescence status are increased in IBD and even more in PSC. These findings may be related to their different tendencies and predisposition to develop malignancy.

Latrophilins a new family of genes contributing to increased airway smooth muscle mass and contraction in asthmatic airways

***A. Faiz**[1,2], C. Donovan[3], B. G. G. Oliver[1,2], A. J. Halayko[4], K. A. Detillieux[4], J. P. T. Ward[5], T. Lee[5], S. D. Wilton[6], J. L. Black[1,2], J. E. Bourke[3], B. E. McParland[2], J. K. Burgess[1,2];*

Asthma is associated with hyper-contractile airways and structural changes in the airway wall, including increased airway smooth muscle (ASM) mass. The aim of this study was to identify genes which may contribute to these processes in asthmatic airways. To compare the gene expression profiles of human primary ASM cells from asthmatic (n=3) and healthy donors (n=3), Affymetrix GeneChip HuGene_1.0_ST Arrays were used. Partek® analysis revealed 11 differentially expressed genes, which were not previously associated with asthma, including latrophilin 3 (LPHN3), a gene thought to be brain specific, which was up-regulated in asthmatic ASM cells compared to healthy donors (3.4 fold p<0.001, n=3). Using qPCR LPHN3 and the family member LPHN1 were both found to be up-regulated in asthmatics (n=16) compared with healthy donors (n=6, p<0.05 and p<0.01, respectively). The microarray predicted a single splice variant of LPHN3 increased in asthmatics which was confirmed by RT-PCR and sequencing. The LPHN1 ligand, α-LTX (toxin produced by black widow spider), increased proliferation of immortalised ASM cells (n=3, 1.21 & 1.20 fold, 0.3nM & 1nM, p<0.01 respectively) and induced the phosphorylation of AKT at 1 min (1nM). Addition of α-LTX (10nM) caused contraction of human airways, while FLRT3 (LPHN3 ligand) had no direct effect. The enhanced expression of LPHN1 in asthmatic airways may contribute to increased proliferation and contractility of ASM. The functional role of LPHN3 in the airways requires further investigation.

Association of the genes involved in xenobiotic metabolism and antioxidant pathways polymorphic markers with development of chronic obstructive pulmonary disease

***G. Korytina**, L. Akhmadishina, T. Viktorova;*
Institute of Biochemistry and Genetics Ufa Scientific Center, Ufa, Russian Federation.

Chronic obstructive pulmonary disease (COPD) is a multifactorial inflammatory disease primarily affecting distal respiratory pathways and lung parenchyma. An oxidant-antioxidant imbalance in the lung contributes to the

development of COPD that is caused by a complex interaction of genetic and environmental risk factors.
The contribution of the 28 polymorphic markers of xenobiotic metabolism and antioxidant pathways genes (CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2E1, CYP2F1, CYP2J2, CYP2S1, GSTM1, GSTT1, GSTP1, NQO1, EPHX1, UGT2B7, SOD1, SOD3, CAT, GPX1) to COPD has been assessed. For this purpose, PCR-RFLP analysis of the xenobiotic metabolism and antioxidant pathways genes polymorphisms in COPD (N=391) and control (N=514) groups has been performed.
The NQO1 rs1131341 was associated with COPD in additive model (OR=2.55 95%CI 1.74-3.75), P=1.012 x 10-6 adjusted for age, sex, pack-years, ethnos). Analysis showed an association of the C-T haplotype of rs1131341 and rs1800566 NQO1 gene polymorphisms
(OR=2.77 95%CI 1.75 - 4.40, P=0.0001) with COPD. The relationship between the CYP2A6 rs71790353 (OR=3.16 95%CI 1.89-5.33, P=0.00001 with normal genotype) and CYP2S1 rs338583 (OR=0.21 95%CI 0.10-0.44, P=0.00001 in recessive model) and COPD risk was found. Significant association with increased rick of COPD was observed for the CAT rs1001179 in recessive model (OR=0.40 95%CI 0.21-0.76, P=0.0035), the EPHX1 rs1051740 in additive model (OR=1.46 95%CI 1.13-1.89, P=0.0034), and the GSTP1 rs1695 in dominant model (OR=1.51 95%CI 1.12-2.04, P=0.00439). We found a significant interaction of the smoking status and CYP1A1 rs1048943 (P=0.047), GPX1 rs1050450 (P=0.041), CYP2F1 rs11399890 (P=0.049) and UGT2B7 rs7439366 (P=0.013).

Background: Down Syndrome patients are predisposed to Congenital Hypothyroidism which may aggravate their mental status.
Objective: To understand the thyroidal dysgenesis mechanisms in a Down Syndrome murine model.
Methods: The transgenic Dyrk1a (TgDyrk1a) mouse has three copies of Dyrk1a. We compared T4 and TSH plasmatic levels of 8-12 weeks old TgDyrk1a and wild type (wt) mice, their thyroid structure and their development from embryonic day (E) 13.5 to E17.5 by immunofluorescence with anti-Nkx2.1 antibody, a marker of early thyroid development and anti-T4 antibody for final differentiation. The transcription factors Nkx2-1 and FoxE1 involved in thyroidogenesis and the thyroglobulin necessary for T4 synthesis were studied by qPCR at these stages.
Results: TgDyrk1a mice have a lower plasmatic T4 (2.4 ng/mL versus wt: 3.7 ng/mL; p = 0.019) and an increased plasmatic TSH (114mUI/L versus wt: 73mUI/L). Their thyroidal follicles surface is larger (6955µm^2 versus wt: 5755µm^2). At E15.5 the primary thyroids are larger (5700000 pix^2 vs wt: 2900000 pix^2; p= 0.01) but their follicular differentiation surface is decreased at E17.5 (1070000 pix^2 vs 2800000 pix^2 in wt, p= 0.01). RNA levels of Nkx2-1(p=0.009), FoxE1 (p=0.025) at E13.5, and Thyroglobulin (p=0.04) at E17.5 are increased.
Conclusions: TgDyrk1a mice have abnormal thyroid development with ultimately mild hypothyroidism. An increase of the transcription factors expression and their target genes involved in thyroid development and function was documented. The young adult thyroids phenotype is probably due to a compensation mechanism. We are studying candidate genes as Dyrk1a targets using thyroidal cell lines.

Familial pulmonary arterial hypertension: BMPR2 gene mutation findings in a Venezuelan family

R. A. Cedeno[1], *G. Vergara*[2], *T. deRavel*[3];
[1]*Genetic Medical Institute, Zulia University, Maracaibo, Venezuela, Bolivarian Republic of,* [2]*Cardiology, Hospital Clinic, Maracaibo, Venezuela, Bolivarian Republic of,* [3]*Medical Genetics, Centre for Human Genetics, Leuvem, Belgium.*

Objectives: The purpose of this paper is to determine the mutations in the *BMPR2* gene in members of one family with a diagnosis of Familial Pulmonary Arterial Hypertension.
Methods: Clinical Evaluation: Written informed consent was obtained from all family members, who underwent pedigree analysis and clinical assessment in accordance with the requirements of the Ethics Committee of the Genetic Medical Institute of Zulia University. Familial pulmonary arterial hypertension was diagnosed with the use of current international consensus criteria, and was determined through clinical evaluation, chest radiography, electrocardiography, Doppler echocardiography and right-heart catheterization. Other known causes of elevated pulmonary arterial pressure were excluded. The diagnosis was established without knowledge of the genotype status. The molecular analysis of the
BMPR2 gene was performed with collaboration with the Centre for Human Genetics, University of Leuven, Belgium.
Results: Analysis of *BMPR2* sequence was performed in three family members with pulmonary hypertension. All were heterozygous for the c.1471C>T mutation in exon 11 of the *BMPR2* gene (at protein level p.Arg491Trp).
Conclusion: The FPAH is less rare than initially believed, in part because of patient and physician awareness of the familial occurrence of the disorder. It is an autosomal dominant disorder that affects females disproportionately, may occur at any age, and is characterized by reduced penetrance and variable expressivity as is seen in this first Venezuelan family report. These results suggest that other endogenous or exogenous factors modify its expression, as is well known.

Contribution of *LHX4* mutations to pituitary hormone deficits in 350 patients presenting with ectopic posterior pituitary and/or *sella turcica* anomalies

M. Legendre[1,2], ***E. Cohen***[1], *N. Collot*[2], *S. Rose*[2], *F. Dastot*[2], *P. Duquesnoy*[1], *B. Copin*[1,2], *M. Vie-Luton*[1,2], *A. Bertrand*[3], *L. Hilal*[4], *J. Leger*[5], *M. Maghnie*[6], *I. Oliver-Petit*[7], *M. Polak*[8], *M. Tauber*[7], *P. Touraine*[9], *M. Sobrier*[1], *S. Amselem*[1,2];
[1]*Inserm UMR_S933 and UPMC Univ Paris 06, Paris, France,* [2]*U.F. de Génétique clinique et moléculaire, Hôpital Trousseau, AP-HP, Paris, France,* [3]*Service de Pédiatrie et d'Endocrinologie, CHU de Besançon, Besançon, France,* [4]*Laboratoire de Biologie générale, Faculté des Sciences, Rabat, Morocco,* [5]*Service d'Endocrinologie pédiatrique, Hôpital Robert Debré, AP-HP, Paris, France,* [6]*Pediatrics, IRCCS G. Gaslini, University of Genoa, Genoa, Italy,* [7]*Service d'Endocrinologie et Génétique, Hôpital des Enfants, CHU de Toulouse, Toulouse, France,* [8]*Service d'Endocrinologie pédiatrique, Hôpital Necker, AP-HP, Paris, France,* [9]*Service d'Endocrinologie, Hôpital Pitié-Salpêtrière, AP-HP, Paris, France.*

To date, only 9 unambiguous *LHX4* mutations have been reported in pituitary hormone deficits. These mutations, always found in the heterozygous state, are responsible for a dominant hypopituitarism with variable expressivity. Several patients displayed an ectopic posterior pituitary (EPP) or a hypoplastic *sella turcica*.
The objective of this study was i) to assess the prevalence of *LHX4* mutations in a large group of patients presenting with various pituitary hormone deficits associated with an EPP and/or *sella turcica* anomalies, ii) to provide a most complete description of the *LHX4* associated-phenotypes, and iii) to assess the functional consequences of the identified variants.
We screened the *LHX4* gene in a group of 350 independent probands and assessed the ability of the identified *LHX4* variants to transactivate the *POU1F1* proximal promoter.
In addition to one previously described mutation (c.538-1G>C), we identified 6 novel heterozygous mutations: 1 nonsense (p.Tyr131X), 1 frameshift (p.Arg48ThrfsX151), 1 splice (c.606+1G>T, *de novo*) and 3 missense variations (p.Ala65Val, p.Arg221Gln and p.Arg235Gln). Posterior hypophysis was eutopic in one patient; EPP was noted in four probands. Three patients showed an abnormal *sella turcica*. Short stature at diagnosis ranged from -2SD to -5SD. Incomplete penetrance was observed in one family (p.Tyr131X). Functional assessment of the identified variants is underway.
This study, performed in the largest cohort of patients so far screened for *LHX4* mutations, shows that this gene is responsible for at most 2% (7/350 independent probands) of hypopituitarisms associated with ectopic posterior pituitary and/or *sella turcica* defects.

TSC1 and TSC2 genotypes and clinical efficacy of everolimus in subependymal giant cell astrocytoma (SEGA) and renal angiomyolipoma (AML) associated with Tuberous Sclerosis Complex (TSC)

D. J. Kwiatkowski[1], *J. J. Bissler*[2], *D. N. Franz*[2], *M. Palmer*[3], *C. Kalfoglou*[4], *S. Segal*[5], *D. Chen*[5], *J. Sampson*[6];
[1]*Brigham and Women's Hospital, Boston, MA, United States,* [2]*Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States,* [3]*Novartis Pharmaceuticals Corporation, Cambridge, MA, United States,* [4]*Novartis Pharmaceuticals Corporation, East Hanover, NJ, United States,* [5]*Novartis Pharmaceuticals Corporation, Florham Park, NJ, United States,* [6]*Institute of Medical Genetics, Cardiff University, Cardiff, United Kingdom.*

TSC is characterized by growth of nonmalignant but often progressive lesions in several organs throughout the body such as the brain (SEGA) and kidneys (AML). Most TSC patients have inactivating mutations in either *TSC1* or *TSC2*, and TSC lesions show constitutive activation of mTOR. The efficacy and safety of everolimus, an mTOR inhibitor, was assessed in two double-blind, placebo-controlled, phase 3 trials: EXIST-1 (SEGA associated with TSC; NCT00789828) and EXIST-2 (AML associated with TSC or sporadic lymphangioleiomyomatosis; NCT00790400). In EXIST-1, patients were randomized to receive 4.5 mg/m^2/day everolimus (n=78) or placebo (n=39) and in EXIST-2, patients were randomized to receive 10 mg/day everolimus (n=79) or placebo (n=39). In each trial, everolimus was superior to placebo for the primary endpoints of SEGA and AML response rates (SEGA: 35.0% vs 0%; P<0.0001; AML: 42.0% vs 0%; P<0.0001) and was associated with an acceptable safety profile. Blood DNA was collected from all patients in both trials and *TSC1* and *TSC2* gene alterations were identified by sequencing of the coding regions for mutations and by Multiplex Ligation-dependent Probe Amplification analysis for genomic deletions. Preliminary results demonstrated no apparent correlation between response rate and mutation categories in either trial (Table). These results suggest that everolimus has a similar clinical benefit in patients, regardless of TSC genotype; further in-depth analysis of genotype-clinical response correlation will be performed.

TSC1/2 Mutation Frequency and Corresponding SEGA and AML Response Rate

EXIST-1				
Gene	Mutation frequency, % (n/N) Everolimus	SEGA response rate, %	Mutation frequency, % (n/N) Placebo	SEGA response rate, %
TSC1	13 (10/77)	50	8 (3/39)	0
TSC2	71 (55/77)	30	74 (29/39)	0
No mutation identified	13 (10/77)	45	18 (7/39)	0
EXIST-2				
Gene	Mutation frequency, % (n/N) Everolimus	AML response rate, %	Mutation frequency, % (n/N) Placebo	AML response rate, %
TSC1	4 (3/79)	50	5 (2/39)	0
TSC2	76 (60/79)	48	69 (27/39)	0
No mutation identified	18 (14/79)	36	26 (10/39)	0

P04.76

A search for new *CYP3A5* and *CYP3A4* variants as determinants of tacrolimus dose requirements in transplanted patients

B. Tavira Iglesias*, F. Ortega, C. Diaz-Corte, V. Álvarez, E. Coto;*
HOSPITAL UNIVERSITARIO CENTRAL DE ASTURIAS, OVIEDO, Spain.

Tacrolimus (Tac) is an immunosuppressive drug used to avoid the rejection of solid organs. *CYP3A5*3* (rs776746) and *CYP3A4*1* (rs2740574) polymorphisms were related with Tac dose requirements. A new variant *CYP3A4* variant (**22*; rs35599367) was recently associated with a significant lower Tac dose requirement. The main aim of this study was to analyze the impact of *CYP3A4*22* on blood Tac levels and dose requirements among Spanish kidney transplanted, and to identify new *CYP3A5* and *CYP3A4* variants that could be related with Tac bioavailability. A total of 206 kidney patients who received a cadaveric kidney and received Tac as primary immunosuppressor were studied. *CYP3A4*22* was genotyped by real time PCR *Taqman* assay, and the *CYP3A5*3* and *CYP3A4*1* polymorphisms through PCR-RFLP. The coding exons (plus intronic flanking bases) of the two genes were sequenced. *CYP3A5**3, *CYP3A4*1* polymorphisms were associated with Tac dose requirements (p<0.05). The *CYP3A4*22* variant did not influence Tac dose and blood levels, nominally and after correcting by the CYP3A5 genotypes. We identified a new missense *CYP3A4* exon 8 variant, p.P227T, in one patient. This was a conserved residue predicted to affect protein function. In conclusion, the absence of *CYP3A5* coding variants suggested that rs776746 (*CYP3A5*1/*3* alleles) was the main determinant of Tac pharmacogenetics in our population. Although rare *CYP3A4* variants were found among our patients, the promoter rs2740574 (*CYP3A4*1/*1B*) was the main modifier of Tac bioavailability at this gene.

A novel homozygous insertion in the NNT gene in a Dutch patient with familial glucocorticoid deficiency (FGD)

O. Jazayeri[1], *X. Liu*[2], *C. C. van Diemen*[1], *B. Sikkema-Raddatz*[1], *R. J. Sinke*[1], *J. Zhang*[2], *C. M. A. van Ravenswaaij-Arts*[1];
[1]*Department of Genetics, University Medical Centre Groningen, University of Groningen, Groningen, Netherlands,* [2]*BGI-Shenzhen, Shenzhen 518083, China.*

Familial glucocorticoid deficiency (FGD; MIM 202200) is a rare autosomal recessive disorder characterized by undetectable or low levels of plasma cortisol despite high plasma adreno¬corticotropin (ACTH) levels. Affected individuals are resistant to ACTH, i.e. the adrenal cortex is not able to produce cortisol in response to stimulation by ACTH.
FGD is a heterogeneous disorder with known mutations in MC2R, MRAP, STAR, CYP11A1 and MCM4. It has recently been indicated that mutations in NNT (nicotinamide nucleotide transhydro¬genase) are also responsible for FGD. NNT is a highly conserved protein integrated in the inner mitochondrial membrane; it appears to be essential for free radical detoxification in adrenocortical cells. Our study provides support for NNT being involved.
We studied a consanguineous Dutch family with one affected boy with FGD, presenting with convulsions and hypoglycaemia at the age of 12 months. In retrospect, he had had a brownish tan due to increased ACTH level since the age of 4 months. His adrenal ultrasound was normal and no mutations could be detected in MC2R and MRAP. SNP haplotyping (300k array) identified a 6.67 Mb homozygous region harboring the NNT gene. Exome-sequencing revealed a novel homozygous frameshift mutation (NM_012343.3: c.1259dupG). This mutation was validated by Sanger sequencing and both his parents were shown to be heterozygous carriers. The mutation is located in exon 9 and creates a frameshift starting at codon His421 and leading to a premature stop-codon (p.His421Serfs*4). It also lies in the mitochondrial matrix domain, which is known to result in FGD when truncated.

P04.78

Contribution of *GH* and *GHRHR* mutations to isolated growth hormone deficiency - Identification and functional characterization of new variants

M. Legendre[1,2], *M. Sobrier*[1], *F. Dastot*[1,2], *N. Collot*[2], *S. Rose*[2], *A. Soleyan*[2], *L. Hilal*[1], *M. Vie-Luton*[1,2], *P. Duquesnoy*[1], *B. Copin*[1,2], *S. Amselem*[1,2];
[1]*Inserm UMR_S933 and UPMC Univ Paris 06, Paris, France,* [2]*U.F. de Génétique clinique et moléculaire, Hôpital Trousseau, AP-HP, Paris, France.*

Although growth hormone (GH) and the GH releasing hormone receptor (GHRHR) have been recognized as key etiologic factors in non-syndromic forms of isolated growth hormone deficiency (IGHD), few mutations have been identified in this rare condition (accounting for 6-12.5% and 0-6.7% of IGHD cases). So far, very few functional studies have been performed.
To assess the contribution of *GH* and *GHRHR* in the pathogenesis of IGHD, we first analyzed these two genes in a large cohort of patients with non-

syndromic forms of IGHD.
GH was studied in 191 independent patients and *GHRHR* was subsequently analyzed in the remaining 144 independent patients (with no identified *GH* defect and available DNA). The GHRH response of GHRHR variants was assessed *in vitro* through a CRE-dependent luciferase assay.
GH mutations were identified in 28 patients (15%), 10 of them (10/191, 5%) representing familial forms of IGHD. These include 7 novel mutations (2 frameshifts, 5 missense). We identified *GHRHR* mutations in 22 patients (15%), 7 of them (7/144, 5%) representing familial cases. The *GHRHR* mutation spectrum (6 truncating, 1 splice, 10 missense) comprises 13 novel mutations. As shown by functional studies, 5 of the *GHRHR* missense variations represent loss-of-function mutations.
Overall, this study performed in a large patient cohort, which identifies molecular defects in *GH* or *GHRHR* in 50 out of 191 independent patients (27%), reveals the importance of those genes in the pathogenesis of non-syndromic IGHD. Noteworthy, 62% (31/50) of the patients with a *GH* or *GHRHR* defect represent sporadic cases.

Pseudo-isodicentric X chromosomes of the short arm of chromosome X (i(Xp) chromosomes) are rare. Most i(Xp)chromosomes occur as a mosaic with a 45,X cell line. Patients with this mosaic genotype have ovarian failure and variable height. We report two patients who presented with proportionate short stature without stigmata of Turner syndrome. Both patients also had hypergonadotropic hypogonadism.
Conventional cytogenetic analysis in lymphocytes revealed the presence of a 46,X,pseudo-isodicentric Xq21.1. FISH analysis showed that the X inactive specific transcript (*XIST*) gene is present twice on the i(Xp)chromosome. In patient 1 the i(Xp)chromosome was demonstrated in all cells next to a normal X-chromosome, while in patient 2 a mosaic was seen in which 10% of the cells harboured a 45,X karyotype, and in 90% of the cells a karyotype with the i(Xp)chromosome was shown.
The presence of two *XIST* genes on the i(Xp) chromosome indicates inactivation of the i(Xp), caused by alteration of the chromatin structure, a process described as inactivation enhancement. The degree of inactivation is correlated with the size of the Xq deletion, with larger deletions being more critical. The inactivation might also concern the PAR regions. This would effectively cause haploinsufficiency of the *SHOX* gene, explaining the short stature in these patients.
Both patients were treated with growth hormone, while patient 1 also received low dose estrogens. This resulted in growth acceleration without increase in bone maturation.

P04.80
A novel chromosomal locus for primary ciliary dyskinesia

R. Parvari[1,2], *M. Mazor*[1], *S. Alkrinawi*[3,1], *V. C. Sheffield*[4], *M. Aviram*[3,1];

Cilia are essential for fertilization, respiratory clearance, cerebrospinal fluid circulation and establishing laterality. Cilia motility defects cause primary ciliary dyskinesia (PCD, MIM244400), a disorder affecting 1:15,000-30,000 births. In a consguineous Bedouin family with 2 affected and 6 healthy siblings we have searched for the mutation causing the disease. Assuming disease by homozygosity of a mutation from a common ancestor, linkage to the *DNAH5* and *DNAI1* genes was excluded by the finding of heterozygosity of alleles at known polymorphic markers adjacent to these genes. We further searched for homozygous regions consistent with linkage by genotyping the patients and both parents with the Affymetrix (Santa Clara, CA) GeneChip® Human Mapping 250K Sty arrays. Five homozygous regions larger than 18cM were identified using the KinSNP program. To determine linkage to a single region, all family members were tested with both known polymorphic microsatellite markers and with additional markers developed for this purpose. Linkage was identified to a chromosomal locus on chromosome 18p11.1-q13.3. The multipoint Lod score calculated was 2.99, using the Pedtool server assuming recessive inheritance with 99% penetrance and an incidence of 0.01 or 0.001 for the disease allele in the population. The region contains 10 genes encoding ciliary proteins, a putative mutation causing PCD was not identified in any of these.

Surprising genetic heterogeneity for primary ciliary dyskinesia in the Irish Traveller population

D. Slattery[1], *P. McGettigan*[2], *A. Reynolds*[3], *B. N. Kennedy*[3], *S. Ennis*[4,5], *S. Lynch*[6,5], *J. P. Casey*[7], ***D. Lambert***[1];
[1]*National Centre for Respiratory Disorders, Children's University Hospital, Dublin 1, Ireland,* [2]*UCD School of Agriculture, Food Science and Veterinary Medicine, University College Dublin, Dublin 4, Ireland,* [3]*Conway Institute, University College Dublin, Dublin 4, Ireland,* [4]*School of Medicine and Medical Sciences, University College Dublin, Dublin 4, Ireland,* [5]*National Centre for Medical Genetics, Our Lady's Children's Hospital, Dublin 12, Ireland,* [6]*Genetics Department, Children's University Hospital, Temple Street, Dublin 1, Ireland,* [7]*National Children's Research Centre, Our Lady's Children's Hospital, Dublin 12, Ireland.*

Primary ciliary dyskinesia (PCD) is a life-limiting multi-organ condition characterised by impairment of muco-ciliary clearance. Identification of the PCD disease mutations in the Irish population would facilitate the development of genetic-based diagnostic tests to allow for earlier definitive diagnosis, earlier treatment and improved long-term outcomes. Currently patients have to travel to the UK for confirmation of diagnosis. We aimed to identify the genetic mutation responsible for PCD in the Irish Traveller population (~26,000), an endogamous nomadic group distinct from the Roma gypsies. Our study involves five affected children from three different families. As each recessive disorder in the Irish Traveller population is caused by a common homozygous mutation, we hypothesised that the three families shared the same PCD disease mutation. Exome sequencing was performed for one affected child from each family. Analysis of the exome data did not identify a recessive deleterious mutation common to the affected children from all three families. Analysis of electron microscopy results supported the genetic findings; each family has a different type of ciliary defect suggesting a different disease gene. The findings have led to a change in study design and the exome data from each family is now being analysed independently. We identified a known PCD disease gene in one family, a novel disease gene in the second family and analysis is on-going in the third family. The results to date suggest that there is more than one PCD disease gene in the Irish Traveller population, which is surprising given the limited population size.

First reported spontaneous pregnancy in autosomal recessive pseudohypoaldosteronism type 1 (PHA1B) complicated by placental insufficiency

Introduction
Pseudohypoaldosteronism (PHA) is characterized by hyperkalaemia, metabolic acidosis and elevated aldosterone levels (Chang 1996). The autosomal recessive form (PHA1B) is due to mutations in three genes, each encoding a sub-unit of the epithelial sodium channel (ENaC) (Chang 1996). This channel is widely expressed on the surface of motile cilia (Enuka 2011) and therefore PHA1B is associated with respiratory infection and infertility.
Case history
We report the case of a 28-year old female with PHA1B, due to homozygous mutations in the *SCNN1A* gene, who became spontaneously pregnant after one year of trying to conceive. A 20-week antenatal scan showed severe intra-uterine growth restriction (IUGR). Continued placental insufficiency and oligohydramnios led to an emergency delivery at 28 weeks. Post-operatively, the mother required treatment for hyperkalaemia with metabolic acidosis as well as a DVT. The baby developed meconium ileus necessitating a bowel resection and a prolonged neonatal intensive care admission.

Discussion
PHA1B causes widespread ciliary dysfunction and infertility (Enuka 2011). To our knowledge, this is the first case of a successful spontaneous pregnancy in a female with PHA1B. We hypothesize that the placental insufficiency in this pregnancy was linked to the maternal PHA1B resulting from the homozygous mutation in the *SCNN1A* gene encoding the α-subunit of ENaC. Therefore, this case illustrates that spontaneous pregnancy is possible in PHA1B. If achieved there should be careful monitoring for the possible complications of maternal metabolic instability and fetal IUGR/prematurity as well as counselling given to the couple to highlight these issues.

Loss of function of DMXL2 causes a complex neuroendocrine disorder with ataxia and mental disability.

*L. Huijbregts[1,2], B. Tata[1,2], M. Amouyal[1], S. Jacquier[1], S. Leka[1], A. Durr[3], E. Genin[4], J. Carel[5,6], J. Leger[1,6], **N. de Roux**[1,2];*
[1]INSERM U676, Robert Debré Hospital, Paris, France, [2]Paris Diderot University, Paris, France, [3]INSERM US975, Paris, France, [4]INSERM U1078, Brest, France, [5]INSERM CIE-5, Robert Debré Hospital, Paris, France, [6]Pediatric Unit, Robert Debré Hospital, Paris, France.

Here, we studied a new phenotype in three brothers born from first cousins of Senegalese origin. Disease onset began in early childhood with growth retardation and asymptomatic hypoglycemia with incomplete suppression of insulin levels. Between 14 and 20 yrs, the three patients developed a slowly progressing non-autoimmune insulin deficient diabetes mellitus, central hypothyroidism and partial hypogonadotrophic hypogonadism. In addition, they exhibited an ataxia and dystonia due to a progressive peripheral sensitive-motor demyelinating polyneuropathy, along with pyramidal manifestations. Brain MRI exposed moderate sub-cortical temporal white matter disease. All three subjects presented a moderately low intelligence quotient, dysarthria, difficulties swallowing and frontal alopecia to different degrees.
A genome mapping followed by high throughput sequencing of two candidate regions found an un-described homozygous in-frame deletion of 15 nucleotides in exon 24 of DMXL2 (c.5827_5841del) leading to the deletion of 5 residues (p.1942_1946del) in the three brothers. The c.5827_5841del homozygous deletion was associated with a significant decrease of DMXL2 mRNA levels in blood lymphocytes. The screening of DMXL2 in 10 additional cases with a similar phenotype did not reveal any new mutation.
DMXL2 encodes for rabconnectin-3α (rbcn3-α) which is a synaptic protein interacting with regulators of the Rab3a "on-off" activity, a vesicle associated protein involved in the regulatory secretion. The production of a Dmxl2-knock-out mouse line confirmed the role of rabconnectin-3α in the central activation of the gonadotropic axis. In-vitro investigation showed its role in regulatory secretion. These data open a new door to understand the postnatal neuroendocrine plasticity leading to puberty.

[1]Leiden University Medical Center (LUMC), department of Pediatrics, Leiden, Netherlands, [2]LUMC, department of Endocrinology and Metabolic Diseases, Leiden, Netherlands, [3]LUMC, department of Clinical Genetics, Leiden, Netherlands, [4]Section on Growth and Development, National Institutes of Health, Bethesda, MD, United States, [5]University of Twente, MIRA institute for biomedical technology and technical medicine, department of Developmental BioEngineering, Enschede, Netherlands, [6]VU University Medical Center, department of Pediatrics, Amsterdam, Netherlands, [7]Radboud University Nijmegen Medical Center, department of Pediatrics, Nijmegen, Netherlands, [8]Canisius-Wilhelmina Hospital, department of Pediatrics, Nijmegen, Netherlands, [9]University of Chile, institute of Maternal and Child Research, Santiago, Chile.

Height is a highly heritable and classic polygenic trait. Recent GWAS have revealed that at least 180 genetic variants influence adult height. However, these variants explain only about 10% of the phenotypic variation in height. In an effort to identify novel genetic variants associated with short stature (SS), we studied 162 patients from 149 unrelated families with SS. To detect copy number variants (CNVs), whole genome SNP array analysis was performed. All potentially pathogenic CNVs (containing protein-coding genes and not described in the Database of Genomic Variants or an in-house reference) were assessed with Ensembl and DECIPHER for gene content and similar cases, respectively. Segregation analysis was performed if possible. Genes in CNVs were compared with information from GWAS, gene expression in rodents' growth plates, and published information. Known or potentially pathogenic CNVs were detected in 39 families; in 6 families a known cause of SS was found (*SHOX* or *IGF1R*), in two combined with a second, potentially pathogenic CNV. In 33 families one or more potentially pathogenic CNVs (n=40) were detected, several of the deleted or duplicated genes may be considered as potential candidate genes for growth disorders, including four genes associated with height by GWAS (*ADAMTS17*, *PRKG2*/*BMP3*, *PAPPA*, *TULP4*). In 9 families, the CNVs occurred *de novo* or segregated with SS. In conclusion, besides 6 CNVs in 6 families (4%) known to be causative for short stature, 40 CNVs in 33 families (22.1%) with possible pathogenicity were identified. Segregation studies and bioinformatic analysis suggested various potential candidate genes.

P04.85
A large novel deletion in the NBD2 domain of the ABCA3 gene causes neonatal respiratory distress, SMDP3.

***A. Singer**[1], C. Vinkler[2], E. Leshinsky-Silver[2], S. Zangen[3];*
[1]Genetic Institute, Ashkelon, Israel, [2]Genetic Institute, Holon, Israel, [3]Intensive Care Unit, Ashkelon, Israel.

The hereditary surfactant metabolism dysfunction disorders (SMDP) are genetically heterogeneous resulting in severe respiratory insufficiency in full-term infants. Surfactant, mixture of lipids (90%) and specific proteins, prevents lung collapse by lowering surface tension in the alveoli, at the end of expiration.
SMDP are associated with mutations in genes encoding the surfactant proteins like SP-C and SP-B and lamellar body biogenesis like ABCA3. SMDP caused by *ABCA3* mutations is inherited as an autosomal recessive disorder. with the majority of affected children dying within 3 months of age. Some infants though, will develop pediatric interstitial lung disease (ILD). Some will improve spontaneously. Genotype-phenotype relationship is not clear.
We present a novel mutation in the *ABCA3* gene associated with neonatal death. She was born at term and developed progressive respiratory distress within a few hours. On day 9th she was mechanically ventilated. On day 59 despite extensive treatment the patient died. Sequencing the entire encoding regions of the ABCA3 revealed a novel homozygous nonframeshift deletion of 24bp in exon 26 in a highly conserved region. The deletion results in a protein shorter by eight amino acids in the NBD2 domain. The parents were found to be heterozygous for this deletion.
Functional data and genotype-phenotype relationship studies are needed in order to allow proper counseling and clinical decisions. Until now, no therapies have been shown to be effective. Lung transplantation has been suggested in patients with milder mutations. Prenatal genetic diagnosis has been offered to the parents in our case.

P04.86
Mutations in *CYP24A1* as a major cause of Idiopathic Infantile Hypercalcemia (IIH).

***A. Molin**[1], N. Coudray[1], G. Abéguilé[1], N. Richard[1], S. Melaabi[1], M. Decamp[1], C. Colson[1], M. Gérard[1], N. Gruchy[1], H. Mittre[1], M. Castanet[2], M. Kottler[1];*
[1]Centre Hospitalier Universitaire, Caen, France, [2]Centre Hospitalier Universitaire, Rouen, France.

Idiopathic infantile hypercalcemia (IIH), also called Lightwood syndrome, is characterized by transient hypercalcemia and hypercalciuria responsible for nephrocalcinosis, with increased levels of 1,25-dihydroxyvitamin D

(1,25-$(OH)_2$-D), and low levels of parathyroid hormone (PTH). Recently mutations in the *CYP24A1* gene encoding for vitamin D-24-hydroxylase, the enzyme responsible for inactivation of the 1,25-$(OH)_2$-D, have been reported, giving a new insight into IIH.
Objectives: To confirm and extend earlier findings, we screened for *CYP24A1* mutations a cohort of 34 patients (index cases) diagnosed with hypercalcemia and low PTH level (<20 pg/mL).
Methods: Biochemical and endocrine analyses were performed using standard methods and *CYP24A* mutations were identified using the routine procedures involved in the laboratory.
Results: We found 9 (5 children and 4 adults) unrelated patients (26.5%) with homozygous (4/9) or compound heterozygous (5/9) *CYP24A1* mutations. We identified seven new mutations and a large deletion encompassing exons 9 to 11. In children, IHH was diagnosed before 2 years (range: birth - 8 months; mean: 4,5 months) with high calcemia level (>3 mmol/l) and low PTH. All presented with nephrocalcinosis. Out of the 4 adults with CYP24 mutations (1 female and 3 males) 2 presented with nephrocalcinosis, and 1 had kidney stones associated with hypercalciuria. All received vitamin D supplementation.
Conclusion: Mutations in *CYP24A1* currently could give a pathogenic explanation for some IIH, and thus constitute caution regarding vitamin D supplementation in infancy.

Genetic testing for MODY: retrospective study of utilisation in the Netherlands

*S. S. Weinreich[1], A. Bosma[1], L. Henneman[1], T. Rigter[1], M. Breuning[2], E. de Koning[3], M. Losekoot[2], **M. Cornel**[1];*
[1]EMGO Institute for Health and Care Research, Amsterdam, Netherlands, [2]Department of Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands, [3]Department of Endocrinology and Department of Nephrology, Leiden University Medical Center, Leiden, Netherlands.

Genetic testing for maturity-onset diabetes of the young (MODY) may be relevant for treatment of patients and for monitoring of their healthy family members. This study describes the current state of genetic testing for MODY in the Netherlands in terms of volume and test positive rate, medical setting, purpose of the test, and age of patients tested. Some analyses focus on the most prevalent subtype, HNF1A MODY.
In total, 1473 mutation scans for HNF4A, GCK, HNF1A and HNF1B were performed in 2001-2010. Cascade testing for a known mutation in family members occurred 290 times, and did not show an increasing time trend. In total about 400 individuals were identified with a MODY mutation. Testing for HNF1A MODY was mostly requested by internists and paediatricians, often from regional hospitals. A substantial proportion (20-28%) of HNF1A MODY probands was over 40 years old at the time of testing.
The number of individuals genetically tested for MODY so far in the Netherlands is low compared to previously predicted numbers of patients. Primary care physicians and clinical geneticists rarely request genetic testing for HNF1A MODY. In 2009-2010 25% of clinical geneticists' requests concerned cascade testing. Doctors' valuation of the test on the one hand and patients' and family members' response to (an offer of) genetic testing on the other hand need to be investigated. There could be a lack of perceived utility of genetic testing for symptomatic patients and/or presymptomatic family members. Efforts may be needed to develop and implement translational guidelines.

Molecular and genetic analysis of autosomal dominant early-onset diabetes in Tunisian families

***A. Amara**[1,2,3], C. Lecoeur[4,5,6], J. Philippe[4,5,6], S. Lobbens[4,5,6], S. Sassi-Houij[2], L. Chaieb[7], A. Saad[2], M. Gribaa[2], P. Froguel[4,5,6], M. Chadli-Chaieb[1,7], M. Vaxillaire[4,5,6];*
[1]Unit of Molecular Endocrinology, Sousse Faculty of Medicine, Sousse University, Sousse, Tunisia, [2]Laboratory of Human Cytogenetics, Molecular Genetics and Reproductive Biology. Farhat Hached University Hospital, Sousse, Tunisia, [3]Higher Institute of Biotechnology of Monastir, Monastir University, Monastir, Tunisia, [4]European Genomic Institute for Diabetes (EGID) FR 3508, F-59000, Lille, France, [5]CNRS UMR8199, Pasteur Institute of Lille, Lille, France, [6]Lille 2 University, Lille, France, [7]Department of Endocrinology and Diabetology.Farhat Hached University Hospital, Sousse, Tunisia.

Background: Maturity-onset diabetes of the young (MODY) is a dominantly inherited non-autoimmune early-onset diabetes, that is characterized by clinical and genetic heterogeneity. At least thirteen genetic subtypes have been described worldwide with important impacts on diagnosis strategy, individual and familial prognosis and pharmacogenomics.
Objective: To identify the genetic aetiologies of early-onset diabetes or MODY in Tunisian families.
Methods: Thirteen diabetic probands (mean age at diabetes diagnosis: 26.6±4.9 years) from families with diabetes segregating in 2-to-3 generations were screened for mutations in *HNF1A, HNF4A, INS, IPF1, NEUROD1* and *GCK* genes by Sanger sequencing and MLPA technique. Two informative negative families were investigated by linkage analysis using SNP microarray genotyping (Illumina Cardio-Metabo BeadChip consisting of ~200,000 SNPs). The MAZEL software was used for SNP selection, and 11,993 SNPs were analyzed by parametric and non-parametric methods in each family.
Results: Direct MODY genes sequencing showed only one probably non-damaging missense mutation in *HNF4A* (p.I453V) in one family. Two independent linkage signals were found, each one in a single family: on chromosome 11 (F1:$Z_{max\text{-}bipoint}$ = 1.986; $Z_{multipoint}$= 2.230) and chromosome 17 (F2: $Z_{max\text{-}bipoint}$ = 1.735). In family F1, a non-parametric analysis confirmed the linkage signal on chromosome 11 (p-val<0.005).
Conclusion: A causal mutation in known MODY genes has been excluded in the studied MODY patients. A thorough exploration of genomic intervals identified by our study in two families, through gene targeted sequencing or whole exome sequencing, will be promising to identify the responsible gene(s) and causal mechanism of the disease.

P04.89
Monogenic diabetes: molecular screening of MODY genes

*E. Marasco[1], A. Aquilano[1], P. Fici[1], A. Di Rocco[1], G. Storci[2], A. Prossomariti[1], C. Fazio[1], M. Bonafè[2], M. Seri[3], **V. Mantovani**[1,3];*
[1]Center for Applied Biomedical Research (CRBA), S.Orsola-Malpighi University Hospital, Bologna, Italy, [2]Department of Diagnostic Experimental and Specialty Medicine, Bologna, Italy, [3]Unit of Medical Genetics, S.Orsola-Malpighi University Hospital, Bologna, Italy.

Maturity-onset diabetes of the young (MODY) is characterized by early-onset non insulin-dependent diabetes mellitus and autosomal dominant inheritance. Although 12 MODY genes are described, only the most frequent MODY2 and 3 subtypes are usually investigated.
We report a mutation screening of GCK, HNF1A, HNF4A, HNF1B and PDX1 genes (MODY1-5) in 283 patients fitting MODY criteria. Gene mutations are investigated by dHPLC and sequencing; large gene deletions are detected by MLPA. 108 different mutations, 44 of which novel, were detected in 143 probands (50.5%). Among the mutated patients, 79% were GCK/MODY2, 14% HNF1A/MODY3, 3% HNF4A/MODY1, 2% PDX1/MODY4 and 2% HNF1B/MODY5. Among GCK mutations, 59 were missense and 7 were non-sense mutations, 5 were splicing and 4 were small indel, 16 mutations were detected in more than one family. Among HNF1A mutations, 13 were missense, 3 were indel and 2 non-sense, 2 variants affected the HNF-4α binding site of the gene promoter. Also in HNF4A gene a mutation disrupting the HNF-1α binding site in the P2 promoter was detected. A patient showed double heterozygous mutations involving both HNF1A and HNF4A genes. Compound heterozygosis for 2 variants of PDX1 gene was detected in a proband. Heterozygous deletion of whole HNF1B gene was found in 2 patients. Our data broaden the knowledge of the mutations repertoire in these genes and assess the relative prevalence of MODY subtypes in our population. However, about half of patients remains without characterization of the gene defect, indicating that additional genes should be investigated.

Neonatal diabetes mellitus (NDM) is a rare form of pancreatic beta-cell dysfunction leading to hyperglycaemia early in life. It belongs to monogenic diabetes with genetic alterations impairing either pancreas development or insulin secretion.

We evaluated phenotype-genotype correlations and clinical outcome in 174 probands with NDM diagnosed before one year of age, referred to the French NDM Study Group from 1995 to 2010. No patient had beta-cell autoimmunity and all had normal pancreas morphology. They were prospectively investigated for alterations in chromosome 6q24 (uniparental isodisomy, duplication, methylation deffect) and mutations in genes encoding K_{ATP} channel *(ABCC8, KCNJ11)* and preproinsulin (*INS).*

The genetic cause of NDM was identified in 128/174 (74%) probands and consisted in 6q24 abnormalities (n=40), mutation in *KCNJ11* (n=43), *ABCC8* (n=31) or *INS* (n=14). Refined neuropsychological and psychomotor investigations evidenced disorders ranging from developmental coordination disorder (particularly visual-spatial dyspraxia) and/or attention deficits to developmental delay and epilepsy (DEND syndrome) in all patients with K_{ATP} channel mutations. On the other hand, intra-uterine growth retardation (92%), early age at diagnosis (median 5 days [1-120]), and developmental defects involving heart, kidneys or urinary tract (22%) were core feature of the 6q24 phenotype. Remission of diabetes occurred in 89 (51%) probands, but recurrence probability was high, without difference between 6q24 and K_{ATP} channel probands (82% vs 86%, p=0·36).

In conclusion, age at onset, birth weight or associated features can guide NDM genetic testing. Neuropsychological and developmental defects are frequent, differ according to the genetic aetiology, and deserve multidisciplinary assessment.

P04.91

Does TCF7L2 gene predicts type 2 diabetes also in Turkish?

D. Erkoc Kaya[1], *H. Arikoglu*[1], *H. Ozdemir*[1], *M. Gonen*[2], *S. Kayis*[3];
[1]Selcuk University, Faculty of Medicine, Department of Medical Biology, Konya, Turkey, [2]Necmeddin Erbakan University, Meram Faculty of Medicine, Department of Endocrinology, Konya, Turkey, [3]Selcuk University, Faculty of Agriculture, Department of Animal Science, Biometry-Genetics Unit, Konya, Turkey.

Type 2 Diabetes Mellitus (T2DM) is one of the most challenging health problems of the 21st century and growing anxiously in time. The Turkish population is no exception to this trend. To date, TCF7L2 gene has been shown to be the strongest association with an increased risk of T2DM with well-replicated results in several different populations. TCF7L2 encodes a transcription factor, involved in Wnt-signalling pathway, a major regulator of cell growth and development. Wnt signaling influences endocrine pancreas development and modulates mature β-cell functions including insulin secretion, survival and proliferation. This study provides valuable information about the Turkish population because it is the only association study between TCF7L2 variants and T2DM in a Turkish population to the best of our knowledge. Genotyping was carried out by PCR-RFLP and PCR-SSCP techniques and six common variants (rs7903146 C>T, rs12255372 G>T, rs7901695 T>C, rs11196205 G>C, rs11196213 C>T and rs3814573 C>T substitutions) were genotyped in 169 non-obese diabetic and 119 healthy individuals. rs7903146 and rs12255372 were significantly associated with T2DM (OR:1.9 [95% CI: 1.15-3.19] *p*=0.005 and OR:2.1 [95% CI: 1.25-3.55] *p*=0.002 respectively). Calculated odds ratios were higher compared with current literature. Remarkably, for all studied SNPs, heterozygote and homozygote rare allel frequencies were observed higher than common allels according to other populations. We consider it is because of our genetic heterogeneity resulting from historical importance of our geographical position which in the center of migration roads. Our results indicate that TCF7L2 might be a strong effector on T2DM development in Turkish, too.

Whole-exome sequencing in Czech MODYX families: first results and implications

P. Dusatkova[1], *M. Fang*[2], *S. Pruhova*[1], *A. P. Gjesing*[3], *O. Cinek*[1], *T. Hansen*[3,4], *O. Pedersen*[3,5,6], *J. Zhang*[2,7], *J. Lebl*[1];
[1]2nd Faculty of Medicine, Charles University in Prague and University Hospital Motol, Prague, Czech Republic, [2]BGI Shenzhen, Shenzhen, China, [3]Novo Nordisk Foundation Center for Basic Metabolic Research, Faculty of Health Sciences, University of Copenhagen, Copenhagen, Denmark, [4]Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark, [5]Institute of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark, [6]Faculty of Health Sciences, Aarhus University, Aarhus, Denmark, [7]T-Life Research Center, Fudan University, Shanghai, China, Shanghai, China.

Maturity-Onset Diabetes of the Young (MODY) is a heterogeneous group of autosomal dominant diabetes clinically characterised by positive family history of diabetes, age at diagnosis before 25 years and negative beta-cell autoantibodies. Although 13 MODY genes are known, approximately 30% of all cases remain genetically unclarified (MODYX). We aimed to identify the genetic cause of diabetes in 6 MODYX families (22 persons) by whole-exome sequencing (WES).

On average, 99.2% of all exons from each individual were sequenced on an Illumina HiSeq 2000. The detected variants in each sample (average 65,816) underwent co-segregation analyses within the family and filtering against databases dbSNP, Exome Variant Server, 1000 Genome Project, HapMap, LuCamp.

While 154 variants identified in 4 MODYX families are further evaluated and compared with data from other MODYX families, causal mutations in previously known MODY genes were found in two families: First, p.Arg235Trp in the HNF1B gene was detected. Although HNF1B disruption is mostly associated with diabetes and cystic kidney disease (Renal Cysts and Diabetes syndrome), the proband did not display any renal anomaly. A second family carried p.Trp113Leu in the HNF1A gene causing HNF1A-MODY. This mutation escaped the previous testing by direct sequencing due to the presence of 2 formerly unknown polymorphisms under the reverse primer suggesting that only one allele was amplified.

First results from WES in MODYX families pointed out that there is a need for constant awareness and regular re-evaluation of both clinical criteria and primer sequences in routine testing of MODY.

Supported by EFSD and NT11402.

Metabolic and genetic cardiovascular risk factors in diabetes mellitus type 2 patients

A. A. Bystrova[1], *A. A. Voitovich*[2], *M. A. Bogdanova*[3], *B. I. Smirnov*[4], *T. S. Razorenova*[3], *E. I. Krasilnikova*[1], *O. A. Berkovich*[1], *E. V. Shliakhto*[1], *V. I. Larionova*[1,3];
[1]St. Petersburg State Pavlov Medical University, Saint-Petersburg, Russian Federation, [2]St. Petersburg State Pediatric Medical University, Saint-Petersburg, Russian Federation, [3]North-Western State Medical University n.a. I.I. Mechnikov, Saint-Petersburg, Russian Federation, [4]St. Petersburg State Electrotechnical University, Saint-Petersburg, Russian Federation.

Diabetes mellitus type 2 (DM2) is closely associated with the development of various cardiovascular complications including coronary artery disease (CAD). The aim of this study was to investigate CAD risk factors specific to DM2 patients. STUDY POPULATION: DM2 patients with CAD, among them 41 male and 134 females (average age 52±10), and DM2 patients without CAD, among them 57 males and 127 females (average age 50±10). Polymorphisms of genes *APOA1* G-75A and C+83T, *APOC3* Sst1, *APOE* epsilon, *APOA5* T-1131C and S19W, *ADRB3* W64R, and *ACE* I/D together with medical history, family history of CAD and DM2, the body mass index, and the serum lipid levels, among them total cholesterol, high density lipoprotein cholesterol, low density lipoprotein cholesterol, very low density lipoprotein cholesterol, triglycerides, and the atherogenic index were studied with the factor analysis and the logistic regression method. RESULTS: The DM2 patients with CAD were older than the DM2 patients without CAD. Also, their body mass index and the levels of high density lipoprotein cholesterol were higher than the same in the DM2 patients without CAD. It is interesting that the elevated levels of high density lipoprotein cholesterol were typical to the female DM2 patients with CAD and not to the males, when analyzed

separately. No one gene polymorphism was associated with higher risk of CAD in the DM2 patients.

P04.94

The adiponectin variants contribute to the genetic architecture of type 2 diabetes in Turkish

H. -. Arikoglu[1], *D. Erkoc Kaya*[1], *H. Ozdemir*[1], *S. Ipekci*[2], *A. Arslan*[3], *S. Kayis*[4], *M. Gonen*[5];
[1]*Selcuk University, Faculty of Medicine, Department of Medical Biology, Konya, Turkey,* [2]*Selcuk University, Faculty of Medicine, Department of Endocrinology, Konya, Turkey,* [3]*Gaziantep University, Faculty of Medicine, Department of Medical Biology, Gaziantep, Turkey,* [4]*Selcuk University, Faculty of Agriculture, Department of Animal Science, Biometry-Genetics Unit, Konya, Turkey,* [5]*Necmeddin Erbakan University, Meram Faculty of Medicine, Department of Endocrinology, Konya, Turkey.*

Adiponectin is a strong candidate gene for type 2 diabetes, since adiponectin modulates insulin sensitivity and plays an important role in regulating energy homeostasis. We aimed to evaluate the contribution of the adiponectin gene polymorphisms in genetic background of type 2 diabetes in a Turkish population. The study included unrelated, non-obese 169 patients and age-BMI-matched 119 non-diabetic individuals with no family history. PCR-RFLP technique was used for ten SNPs genotyping. We detected significant association with type 2 diabetes and SNPs -11391G>A and -11043C>T in proximal promoter region and SNP +276G>T in intron 2 of adiponectin gene (P<0.05). The silence SNP +45T>G in exon 1 and SNP +349A>G in intron 2 showed weak association with disease (P=0.06 and P=0.07, respectively). We consider that SNPs in proximal promoter might be important in disease development by changing adiponectin expression. The effect of other associated SNPs is unclear, possibly that it may be in interaction with other known or unknown SNPs and/or genes. Also, one of rare SNPs, Y111H was associated with fasting insulin (P<0.05) while other SNP R112C was effective on fasting glucose, fasting insulin and HbA1C (P<0.05). We observed that Y111H and R112C polymorphisms may be severely effective on glucose and insulin levels even in heterozygote form in an individual. Especially R112C, was associated with impaired multimerization and possibly with impaired secretion and/or action of adiponectin since its localization. Consequently, adiponectin gene polymorphisms in Turkish population might contribute to genetic background of type 2 diabetes.

P04.95

Association between TCF7L2 gene polymorphisms and haplotypes with risk of type 2 diabetes in the Iranian population

P. Keshavarz;
Center for Cellular and Molecular biology, Guilan University of Medical Science, Rasht, Islamic Republic of Iran.

TCF7L2 is a transcription factor influencing the transcription of several genes thereby exerting a large variety of functions within the cell. There is strong evidence from several previous studies that two common variants of *TCF7L2* (rs7903146 and rs12255372) are associated with type 2 diabetes. We examined the impact of rs7903146, rs12255372 and rs11196205 variants of TCF7L2 gene and the haplotypes involving these variants on type 2 diabetes in an Iranian genetic association study. We genotyped the three polymorphisms in 537 type 2 diabetic case and 441 control subjects by TaqMan assay. In logistic regression analysis adjusted for age, sex and BMI, the allele frequency of rs7903146 and rs12255372 were significantly different between type 2 diabetes patients and control subject ($p=6.8 \times 10^{-10}$ and $p=9.3 \times 10^{-11}$ respectively). In genotype frequency comparison, the most significant association was obtained under a dominant genetic model for rs7903146 and rs12255372 variants ($p=9.6 \times 10^{-10}$ and $p=3.8 \times 10^{-10}$ respectively). In haplotype analysis the CGG haplotype of TCF7L2 rs7903146-rs11196205-rs12255372 variants showed significant association with type 2 diabetes in our study subjects ($p=1.1 \times 10^{-5}$). In conclusion, we found a strong association of TCF7L2 variants and a three-marker haplotype with development of type 2 diabetes in the Iranian population

P04.96

Does summation of alleles account for genetic risk and genotype-phenotype association in Type 2 Diabetes Mellitus?

N. P. Pace[1], *A. Al Ashtar*[1], *J. Vassallo*[2], *A. E. Felice*[1];
[1]*Laboratory of Molecular Genetics, University of Malta, Msida, Malta,* [2]*Department of Medicine, University of Malta, Msida, Malta.*

Introduction: Type 2 diabetes (T2DM) and metabolic syndrome are common complex disorders with a high prevalence in the Maltese population. The aim of this study is to further define the genetic interplay between cognate genes from metabolic and inflammatory pathways on the likelihood of developing T2DM in adulthood and to relate the association of certain genetic profiles with defined biological and clinical endpoints.
Method: Eight hundred carefully characterised T2DM cases were recruited. Anthropometric and biochemical parameters, including serum high-sensitivity C-Reactive protein (hsCRP) levels were determined, and genotyping of 43 cognate genes carried out. Neonatal cord blood samples were used as the control reference population in this study.
Results: Ten polymorphisms in metabolic/inflammatory pathways showed significant association with T2DM. Three loci showed significant association with lipid profile, body weight and hsCRP levels. hsCRP levels demonstrated a strong positive correlation with body mass index. Genetic score analysis showed that combining multiple genetic markers results in higher relative risks. The functional significance of these polymorphisms is being further evaluated using targeted siRNA-mediated silencing in cultured monocytes.
Conclusion: A panel of ten candidate genes has consistently demonstrated significant association with type 2 diabetes and metabolic syndrome in the Maltese population. These gene variants serve functional roles in inflammation and adipose tissue function. A recruited cohort of untreated newly-diagnosed T2DM serves to identify and explore genotype-phenotype association. The strong effect sizes of these alleles could be used to develop personal genetic susceptibility profiles for T2DM leading to personalization of care and prevention of chronic complications.

P04.97

Analysis of the WFS1 gene promoter polymorphisms as putative risk factors of diabetes mellitus

N. Németh, *Z. Elek, S. Prokop, A. Somogyi, M. Sasvári-Székely, Z. Rónai;*
Semmelweis University, Budapest, Hungary.

Wolframin is a transmembrane protein of the endoplasmic reticulum (ER) playing a role in maintaining ER homeostasis. The protein is coded by the *WFS1* gene, loss-of-function mutations are responsible for the monogenic DIDMOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy and deafness), whereas polymorphisms of the gene were suggested to be risk factors of diabetes mellitus.
Our aim was to investigate the association of two promoter polymorphisms, the rs4273545 single nucleotide polymorphism (SNP) and the rs148797429 insertion/deletion variant (ins/del) with diabetes mellitus. 452 patients and 484 healthy controls took part in the study, genotypes were analyzed by PCR-RFLP and allele-specific amplification. Statistical analysis was carried out using khi-square statistics, linkage analysis was done by the Haploview software.
The rs4273545 G/T SNP showed a significant association with type 2 diabetes (T2DM), even after correcting for Bonferroni ($p = 0.00034$, OR = 1.343), but not with type 1 form of the disease (T1DM). No significant association was found however between the ins/del and either T1DM or T2DM. Linkage analysis revealed linkage disequilibrium between the SNP and the ins/del ($D' = 0.97$; $R^2 = 0.78$), moreover a combined analysis of the two loci demonstrated that the rs4273545T-rs148797429ins haplotype showed an increased risk for T2DM ($p = 0.0004$, OR = 2.410).
In silico analysis suggested that these two polymorphisms are in a GC-rich region possibly altering the methylation status of the promoter region and influencing the binding of transcription factors (e.g. Sp1). *In vitro* functional analysis using luciferase reporter constructs is in progress.

P05.001

A combination of inherited CNVs of unknown significance: Could it be responsible for severe phenotype?

M. Hančárová[1], *T. Mařík*[1], *M. Trková*[2], *K. Männik*[3], *A. Kurg*[3], *Z. Sedláček*[1];
[1]*Department of Biology and Medical Genetics, 2nd Faculty of Medicine, Charles University and University Hospital Motol, Prague, Czech Republic,* [2]*GENNET, Prague, Czech Republic,* [3]*Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.*

Microarrays can identify CNVs associated with intellectual disability (ID). The assessment of causality of inherited aberrations is difficult. We report an affected boy in whom a combination of inherited CNVs was likely pathogenic.

The patient showed severe ID, speech delay, ADHD, seizures, microcephaly, craniostenosis, strabismus, hypotonia, lower limb deformities, atypical fat distribution, facial dysmorphism (hypertelorism, high nasal bridge, broad nose, small mouth, thin lips, long philtrum, small chin, low-set ears), asthma and allergies. His karyotype was normal. SNP array analysis revealed 4 large CNVs: 0.8 Mb dup5p13.2, 1.4 Mb del13q12.12, 0.9 Mb dup19p13.3, and 2.9 Mb del14q32.2. The large del14q32.2 was maternal and the remaining 3 aberrations were paternal. The parents were mildly affected, both attended a special school. The mother had a similar phenotype with dysmorphism, speech disorder, craniostenosis, asthma and allergy.

The maternal deletion involved zinc finger protein gene BCL11B highly similar to BCL11A, the candidate for the 2p15-p16.1 microdeletion syndrome. The paternal dup19p33.3 affected 33 genes including ID candidates MAP2K2, EEF2 and HDGFRP2.

The presence of 2 CNVs of unknown significance larger than 500 kb is 8x more likely in ID patients than in controls. CNVs tolerated in mothers can cause ID in sons. This and the milder parental affection, large CNV size and involvement of candidate genes suggest that the combination of CNVs could cause the severe phenotype in our patient. The combination might exceed the tolerable load of genetic hits and/or transfer them to a sensitive genetic background.

Supported by CHERISH, NT/14200, 00064203 and SF0180027s10.

P05.002

Further delineation of 12p13.33 micro deletions: Two families with small overlapping deletions.

J. E. Liebelt[1], *K. Stallard*[1], *J. Nicholl*[2], *W. Waters*[2];
[1]*South Australian Clinical Genetics Service, Adelaide, Australia,* [2]*SA Pathology, Cytogenetics, Adelaide, Australia.*

12p13.33 microdeletion, associated with intellectual disability (ID), specific language impairment and psychiatric manifestations has only been described in a handful of case reports. We report 2 families with overlapping, but not identical small microdeletions on chromosome 12p13.33, who presented with features consistent with the previously published cases. Array CGH was performed using BlueGnome Cytochip oligo ISCA (4080-5) 8x60K array. Family one consists of an affected mother in whom the deletion has occurred de novo and her 2 affected daughters. They have a 896kb deletion at 12p13.33 [chr12:1,972,757-2,868,481 (hg18)]. involving the CACNA1C, DCP1B, FKBP4, ITFG2, NRIP2, FOXM1 and C12orf32 genes. The mother has mild ID with prominent psychiatric issues whilst her 2 daughters have mild ID and significant speech issues. Family two consists of an affected mother (parents unavailable for testing) and her affected son and daughter. They have a 1.35Mb deletion at 12p13.32-p13.33 [chr12: 2,117,194-3-,469,086 (hg18)]. Involving the CACNA1C, DCP1B, FKBP4, ITFG2, NRIP2, FOXM,C12orf32, TULP3, TEAD4 and TSPAN9 genes. All have mild ID with prominent speech issues. To date these are the smallest deletions identified in the 12p13.33 region and may assist in localizing the genes responsible for the neurodevelopmental aspects of the phenotype. Despite partial or total deletion of CACNA1C, none of the affected individuals have symptomatic or ECG findings consistent with Brugada syndrome, suggesting that haploinsufficiency of this gene is not enough to cause this condition.

P05.003

12q12 deletion syndrome: new perspective on the genetic cause of the phenotype

E. O. Carlsen, *D. Misceo, M. Fannemel, E. Frengen;*
Department of Medical Genetics, Oslo University Hospital, University of Oslo, Oslo, Norway.

We present a 9 year old boy with post-natal growth delay (2,5th centile) and delayed skeletal age, mild-moderate intellectual impairment, problems with limb coordination and hypotonia of the limbs. He manifests dysmorphic features: broad forehead, strabismus, low-set ears, broad mouth, small hands and feet, pectus excavatum, widely spaced nipples.

The karyotype of the patient was concluded to be 46,XY,t(7;8)(p12.1;p12), not disrupting any known genes on chr8. The breakpoint on chr7 may be disrupting *POM121L12*, (mapping in progress) which has as yet unknown function. aCGH (244k) performed on the patient detected a deletion of 12q12 (1,1 Mb chr12:44,830,147-45,964,945, hg19), encompassing the genes *NELL2, DBX2* and *ANO6* as well as the pseudogene *PLEKHA9*. Four previously described patients with overlapping deletions share most of the dysmorphic features and the growth- and mental retardation seen in our patient.

We suggest that the loss of *NELL2* may contribute to the growth delay, because it is upregulated in the epiphyseal plates of broilers with excessive growth and is likely a part of the CNS also controlling skeletal development in addition to neuronal differentiation and mitogenesis. It is also coupled to protection and proliferation of neurons in the hippocampus and cerebral cortex, and Nell2-deficient mice have been shown to have impaired spatial learning memory. Thus, *NELL2* may contribute to the intellectual impairment in the patient. *DBX2* might contribute to the psychomotor delay, as *DBX2* is involved in determining the fate of interneurons in the ventral spinal cord controlling motorneurons, as well as in early neural plate patterning.

P05.004

Dysregulation of *FOXG1* pathway in a 14q12 microdeletion case.

O. Perche[1], *G. Haddad*[2], *A. Menuet*[3], *P. Callier*[4], *M. Marcos*[1], *S. Briault*[1], *B. Laudier*[1];
[1]*Centre Hospitalier Régional d'Orléans - CNRS - UMR7355 - University of Orleans, Orleans, France,* [2]*Genetic Department, Hospital of Blois, Blois, France,* [3]*CNRS - UMR7355 - University of Orleans, Orleans, France,* [4]*Cytogenetics Department, CHU de Dijon, Dijon, France.*

„*FOXG1* syndrome" includes postnatal microcephaly, severe mental retardation with absence of language and agenesis of the corpus callosum. When the syndrome is associated with large 14q12q13 deletions, the patients present characteristic facial dysmorphism. Although all reports were based on genomic analysis, recently a *FOXG1* regulatory elements deletion associated with a down expression of mRNA suggested an implication of *FOXG1* pathway. Herein, we report the case of a young boy with a phenotype consistent with a „*FOXG1* syndrome". He had a *de novo* translocation t(6;14)(q22.1;q12) associated with a heterozygous 14q12.2q13 deletion encompassing *FOXG1*. Subsequently, we investigated his transcriptomic profile on lymphoblastoïd cell lines and/or fibroblasts and showed that *FOXG1* was commonly down-regulated. Moreover, several other *FOXG1* pathway genes were also disturbed. Our data and review of previous reports highlight dysregulation of *FOXG1* pathway as the cause of the „*FOXG1* syndrome" developmental disorder.

Chromosome 15's proximal long arm is a region rich in duplicons, defining

five breakpoints for 15q rearrangements. 15q11.2 microdeletion between BP1 and BP2 has been previously associated with developmental delay and behaviour issues. This region contains four highly-conserved and non-imprinted genes: *NIPA1, NIPA2, CYFIP1, TUBGCP5*. Our goal is to refine the phenotype associated with this microdeletion in a large cohort of patients.
Prevalence of this CNV is 0.8% in patients presenting with developmental delay, behaviour issues and/or multiple congenital malformations, analysed by array-CGH in 4 different French Genetic laboratories. After exclusion of patients presenting an associated genetic alteration (known CNV, aneuploidy or point mutation in a known gene), we collected data from 49 unrelated patients.
67.5% of the patients presented with mild or moderate developmental delay, 82% had speech impairment and 60% had behaviour issues (Attention Deficit and Hyperactivity Disorder, Autistic Spectrum Disorder or Obsessive-Compulsive Disorder). Seizures were described in 19% of the patients and 16% had an associated non specific congenital heart disease.
Parents were analysed in 55 % of the families. In those families, 29 % of the microdeletions were inherited from one of both parents, who did not present any of the features associated with the deletion.
Our results support the hypothesis that 15q11.2 (BP1-BP2) microdeletion is associated with developmental delay, abnormal behaviour, generalised epilepsy and congenital heart disease, although this latter finding had not been previously reported.
However, incomplete penetrance and variability of expression amongst patients are frequent and would require further studies to be assessed.

Copy-number variations at 16p11.2 in Estonian patients

P. Tammur[1], *T. Reimand*[1,2,3], *O. Žilina*[4,1], *I. Talvik*[2,5], *P. Ilisson*[1], *T. Ilus*[1], *P. Toit*[1], *K. Kuuse*[1], *K. Õunap*[1,2];
[1]*Department of Genetics, Tartu, Estonia,* [2]*University of Tartu, Department of Pediatrics, Tartu, Estonia,* [3]*University of Tartu, Institute of Biomedicine, Department of Human Biology and Genetics, Tartu, Estonia,* [4]*Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia,* [5]*Children's Clinic of Tartu University Hospital, Tartu, Estonia.*

There are many copy-number variations (CNVs) associated with genomic disorders with extreme phenotypic heterogenity. One of such CNVs is duplication-deletion at 16p11.2. This syndrome seems to be as frequent as microdeletion/duplication 22q11.2.
Both deletions and duplications at 16p11.2 have been associated with intellectual disability and language impairment. In case of duplication, underweight and intellectual disability is observed contrary to deletion, where obesity and autistic features are main symptoms. It is shown previously that clinical symptoms in carriers of the deletion/duplication represent opposite manifestation mediated by gene dosage.
From January 2012 until January 2013 we performed 667 CNV analyses (HumanCytoSNP-12 v2-1 BeadChips; Illumina Inc.) and found microdeletion/duplication at 16p11.2 in 10 (1.4%). At the same time we diagnosed in 5 (0,75%) patient with microdeletion/duplication 22q11.2.
Here we describe 11 Estonian patients with CNV at 16p11.2. Three cases were with duplication and 8 with deletion in that region. The length of changes varies between 0.2Mb-0.8Mb.
All patients show developmental delay and language impairment in different severity. As expected, dysmorphic features are presented in very minor scale. In one family two brothers had inherited the deletion from father. In one case the duplication was inherited from mother. All parents are not clinically investigated yet.
16p11.2 microdeletion/duplication syndrome is surprisingly frequent in Estonian population. It seems to be even more frequent CNVs than 22q11.2 microdeletion/duplication. Such finding can be explaned by the fact that since 2012 chromosomal microarray is a first-tier clinical diagnostic test for individuals with developmental disabilities and/or congenital anomalies.

The ~600kb 16p11.2 deletions and duplications are among the most frequent genetic etiologies of neurodevelopmental disorders. These recurrent rearrangements are associated with mirror phenotypes such as obesity and underweight, macro- and microcephaly, autism spectrum disorder (ASD) and schizophrenia (SCZ). In 16p11.2, as well as in other genomic disorders, reports of variable expressivity and "incomplete penetrance" have hampered genetic counseling and patient management.
To better understand this variability, we compared the effects of deletions and duplications through a systematic assessment of large cohorts of 16p11.2 rearrangements' carriers (Simons VIP and Europe consortia: n= 287 del, 301 dup). The deletion consistently impacts neurodevelopment, regardless of ascertainment. It is associated with a decrease in full scale IQ (FSIQ) of two standard deviations and frequently causes specific language difficulties. Psychiatric co morbidities are present in the majority of carriers, and seizures are observed in 24% of deletion carriers. We identified an increased velocity of head circumference growth during infancy, which recapitulates the well-documented pattern seen in ASD. In contrast, duplication carriers have a broader range of IQ when compared with deletion carriers (increased rates of FSIQ below 50 and above 100: OR=3.5, p=0.002): this heterogeneity is associated in part with ascertainment method. The association of the duplication with decreased head circumference is similarly influenced by ascertainment, suggesting that the phenotypic heterogeneity might be caused by an interaction between the duplication and other genetic and/or environmental factors. Additional genetic variants that could underlie these observations are currently under investigation.

Interstitial deletions of the proximal long arm of chromosome 16, involving bands 16q11 to 16q13, are rarely reported. With the global implementation of the array-Comparative Genomic Hybridization (array-CGH) technique, the reported cases can now be well characterized at a molecular level, with exact breakpoint establishment. Despite some phenotypic variability, the few reported cases with 16q deletion present some common features, like developmental delay, abnormally shaped ears, hypotonia, limb anomalies and dysmorphisms.
We report a 9 year old female patient with a *de novo* 3.9Mb deletion at chromosome 16q12.1, detected by array-CGH using an Agilent 180K oligonucleotide. She presented with short stature, renal bilateral anomaly, development delay, hypotonia, facial dysmorphisms and precocious puberty.
The reported deletion contains 18 genes, one of which is *SALL1*, whose mutations cause Townes-Brocks syndrome (TBS), a rare dominant developmental disorder characterized by anal, renal, limb and ear malformations. The few reported patients with 16q12.1 deletions have in common the loss of *SALL1* gene, but they do not meet the clinical criteria for being diagnosed as having TBS. In the literature, it has been suggested that TBS is caused by a dominant negative mutation of the gene, whereas haploinsufficiency results in a milder phenotype, like the ones observed in patients with the deletion including our patient. The deletion of adjacent genes might contribute to the phenotypic variability that is observed among these patients.
Report of further patients is necessary in order to define the critical region and the candidate genes responsible for this new 16q12.1 microdeletion syndrome.

P05.009
Duplication-Deletion-Duplication 17p13.3 with the smallest reported deletion of YWHAE

B. L. V. L. Dupont JM, *I. A. G. N. JM Dupont;*
: Laboratoire de Cytogénétique, APHP, Hôpitaux universitaires Paris Centre, France., Paris, France.

Microdeletion of 17p13.3 involving YWHAE (14-3-3-epsilon), but distal to PAFAH1B1, is a newly recognized syndrome associated with variable disorders of cortical development and facial dysmorphism. More recently, both microdeletions and microduplications mapping to this region have been identified. Clinical characterization has been reported according to the length and the genes involved in such rearrangements.
we report on a boy presenting with seizure, learning difficulties and foot abnormalities.Array comparative genomic hybridization (oligonucleotide array-CGH Nimblegen) showed a complex rearrangement with six breakpoints on 17p13.3: Duplication-Deletion-Duplication. Deletion of 30 Kb included only the last exon of YWHAE. First duplication of 380 Kb involved NXN, TIMM2, ABR genes and the second of 164 Kb involved CRK, MYO1C, INPP5K, PITPNA genes. Quantitative PCR was performed to confirm the rearrangement and to show that was absent in both parents and therefore occurred de novo.
We are able to review and refine the molecular and clinical features of recently described novel microdeletion and microduplication on 17p13.3. We report the smallest deletion of YWHAE described. This gene is encoding a highly conserved protein that has been shown to play a crucial role in neuronal development and synaptogenesis. We compare critical regions delineated and candidate genes proposed in cohorts with the aim of refining the phenotype-genotype correlation.
Breakpoints of this non recurrent complex genomic rearrangement were not associated with low-copy repeats and are therefore probably due to replicative mechanism such as Fork Stalling and Template Switching (FoSTeS) or Microhomology Mediated Break Induced Replication (MMBIR).

19q13.11 Microdeletion Syndrome due to an apparently balanced *de novo* chromosome rearrangement: Characterized by high-density SNP array analysis

C. A. Venegas[1], *K. Nieto*[2], *F. Fernandez*[1], *J. Berumen*[1], *S. Kofman*[1];
[1]*Hospital General de Mexico, Mexico. D.F, Mexico,* [2]*Facultad de Medicina. UNAM, Mexico. D.F, Mexico.*

Background: 19q13.11 Microdeletion Syndrome [OMIM#613026] is an emerging disorder characterized by pre-postnatal growth retardation, developmental delay, microcephaly, minor facial dysmorphic features, and signs of ectodermal dysplasia, extremity malformations, and genital abnormalities in males (hypospadias). Using SNP array we detected a 19q13.11 microdeletion in a patient with apparently balanced *de novo* cytogenetic rearrangement between chromosomes 2p35 and 19q13.11. **Methods and Results:** We study a male patient of 6 years 7 months old age with all principal features of 19q13.11 microdeletion syndrome. By cytogenetic-FISH analysis identify to *de novo* apparently balanced non-reciprocal t(2;19) (p35;q13.11). Using 250 k Nsp SNP array we detect a *de novo* interstitial 19q13.11 pat deletion of ~2.54 Mb. To the further characterized the extent of deletion was analyzed by high-density 6.0 SNP array, and found a 2,489,839 pb deletion, the proximal and distal breakpoints at (33,565,628-36,055,467). We realized genotype-phenotype correlations of our patient with eight previously published cases, and two annotated in DECIPHER database, refining the critical region to ~517 kb (chr19:34,919,268-35,436,076), containing 9 RefSeq genes (*UBA2, WTPI, SCG2B2, ZNF302, ZNF181, ZNF599, LOC400685, LOC100652909,* and *ZNF30*). This genomic region was further analyzed the probability of gene haploinsufficiency; resulting *UBA2* as the most significant gene for the phenotype; including the male genital abnormalities. **Conclusions:** To our knowledge, this is the first case report of 19q13.11 deletion syndrome due to an apparently balanced de novo chromosome rearrangement. In addition, we propose that *UBA2* may be responsible for the core phenotype of this novel microdeletion syndrome.

In a fetus exhibiting absent nasal bone, a proximal duplication of chromosome 1 long arm was first identified on karyotype, associated with a 16p11.2 deletion secondary characterized by array-CGH. Duplication was shown to be paternally inherited. Whole chromosome 1 painting probe in both excluded a translocation or an insertion elsewhere. Oligoarray-CGH on amniotic fluid characterized the 1q21.1q21.2 duplication of 5,8Mb with father's identical breakpoints. Furthermore a 16p11.2 deletion of 545Kb was revealed that was unexpectedly maternally inherited and identical.
Paternal history was noteworthy for placement since 6 months-old in host families because of his parents inability to take care of him. Language delay was noted at 3 years. Proband's mother was adopted at 1 month-old. Language delay and learning difficulties were observed associated with overweight.
In early development, proband presented epilepsy and axial hypotonia followed by psychomotor retardation. Absence of nasal bone was confirmed. The boy exhibited macrocephaly, dysmorphy and congenital anomalies.
Thus, we report a case with two inherited chromosomal rearrangements resulting in exacerbation of neurodevelopmental phenotype compared to his parents. Described 1q21.1 duplication is associated with developmental anomalies and macrocephaly notably because of the *HYDIN* paralog gene (Brunetti-Pierri *et al*, 2008). The 16p11.2 deletion, a novel microdeletion syndrome is associated with abnormal behaviour, mental retardation and macrocephaly (Walters *et al*, 2010, Nature, and Jacquemont *et al* 2011, Nature). We will discuss the fact that occurrence of additional chromosomal events, as described in the proband, may be involved in variable expressivity and clinical heterogeneity as observed in the family.

P05.012
1q21.1 microduplication syndrome in a boy and his father

M. Havlovicova[1], *M. Simandlová*[1], *Z. Slámová*[1], *J. Drábová*[1], *M. Hrdlička*[2], *Z. Sedláček*[1];
[1]*Department of Biology and Medical Genetics , University Hospital Motol and 2nd Faculty of Medicine, Charles University Prague, Prague, Czech Republic,* [2]*Department of Paediatric Psychiatry , University Hospital Motol and 2nd Faculty of Medicine, Charles University Prague, Prague, Czech Republic.*

Chromosomal band 1q21.1 can be divided into two distinct regions, proximal and distal, based on segmental duplications that mediate recurrent rearrangements. Microdeletions and microduplications of the distal region within 1q21.1 are susceptibility factors for a variety of neurodevelopmental phenotypes and distinct dysmorphic features.
We present a 6 years old boy with severe intellectual disability, ASD, significant speech delay, hyperactivity and macrocephaly. He comes from 3rd pregnancy complicated by preeclampsia , diabetes and excessive obesity of the mother (there were 2 sponatenous abortions from another partnership of the mother). His early development was delayed- walking unattended at 18 months of age. He exhibits significant facial dysmorphism: macrocephaly with prominent forehead, long face, arched eyebrows, periorbital fullness, epicanthal folds, broad nasal bridge, upturned nose, deep philtrum . His extremities are relatively short with short fingers, he also has hypoplastic genitalia.
The extent of the duplication of our patient is 2.3 Mb , affecting 32 HGNC genes, chr1:144.510.930 - chr1:146.812.122.(hg18)
His father is a carrier of microduplication confirmed by FISH analysis, the exact extend will be confirmed by array CGH method. He has borderline intelectual capacity, his facial features are almost normal.
Consistent phenotypic differences haven't yet been described between people with different-sized microduplications - and people in the same family with the same size microduplication can have very different features.

P05.013
1q44 microdeletion in a Czech boy

M. Simandlova[1], *M. Havlovicová*[1], *M. Hančárová*[1], *J. Drábová*[1], *Z. Slámová*[1], *M. Kynčl*[2], *Z. Peřinová*[3], *Z. Sedláček*[1];
[1]*Department of Biology and Medical Genetics, 2nd Faculty of Medicine, Charles University and University Hospital Motol, Prague, Czech Republic,* [2]*Department of Radiology, 2nd Faculty of Medicine, Charles University and University Hospital Motol, Prague, Czech Republic,* [3]*Department of Neurology, 2nd Faculty of Medicine, Charles University and University Hospital Motol, Prague, Czech Republic.*

The 1q44 microdeletion syndrome is a newly described syndrome first reported by De Vries et al (2001). It is associated with facial dysmorphism, developmental delay (in particular delay of expressive speech), seizures and hypotonia. The most common facial features include microcephaly, hypertelorism and thin upper lip. Abnormal corpus callosum (agenesis, hypogenesis or slightly reduced thickness) is observed in some affected patients. Our patient is a 6-year-old boy with a de novo deletion of 1q44 of about 800 kb (242,951,908-243,763,883, hg18). He was born from the 3rd pregnancy (two previous pregnancies ended by spontaneous abortion). The psychomotor development of the boy is delayed (sitting at 12 months, walking attended by both hands from 18 months, unattended at 3 years, he understands simple sentences but does not speak understandable words). He suffers from seizures developed at the age of 2 years (first two seizures were during fever, since 3 years of age the seizures are short, with wrapping up and turning blue in the face). MRI showed normal corpus callosum, but small changes in white matter. The deletion of our patient is one of the shortest published so far, affecting only 5 genes (FAM36A/COX20, NCRNA00201, HNRNPU, EFCAB2 and a part of KIF26B), and his clinical picture helps to define the phenotypic spectrum of the syndrome. Supported by CHERISH, NT/14200 and 00064203.

P05.014
Fulminant Hepatic Failure associated with Phelan McDermid syndrome

R. Pourová, *P. Hedvičáková, J. Drábová, M. Simandlová, Š. Vejvalková, M. Malíková, D. Novotná;*
University Hospital Motol, Prague, Czech Republic.

Phelan McDermid syndrome is caused by 22q13.3 deletion and its typical features are severe intellectual disability, absent or poor speech development, decreased pain-sensitivity, hypotonia and mild facial dysmorphism. The syndrome could also comprise autistic features, seizures or thermoregulation problems. Rare symtoms are hearing loss, genitourinary anomalies and congenital heart defect. Extremely rare is association of Phelan McDermid syndrome and hepatic failure in early childhood. There have been described only 2 patients with this condition so far. In these cases PIM3 gene (localized in 22q13.33) was considered to be responsible.
We present 7 patients (2 males and 5 females) with Phelan McDermid syndrome. Age at diagnosis ranges from 10 month to 55 years and deletion extent varies from 0.4 Mb to 7.6 Mb. All patients present common features of the syndrome, but they differ in inconstant sypmtoms. Any correlations between phenotype and deletion range haven't been observed.
Patients have been diagnosed using FISH and MLPA, deletion extents were proven by oligonucleotide arrayCGH.
There are 6 patients with deleted PIM3 gene in our group, including two adult patients, but only one of these patients (10-year-old boy with 1.9 Mb long deletion) has developed hepatic failure recently. Therefore simple PIM3 deletion doesn't seem to be the cause of hepatic failure.
The possible mechanism is an alteration of the gene on the other allele, epigenetic factors or mutation in some modifier genes. We discuss potential benefit of whole exome sequencing to further elucidate mechanism in these patients.
Support: Czech Ministry of Health project 00064203.

P05.015
2q24.3 deletion involving SCN1A in a patient with profound multiple disabilities and severe epilepsy

S. Grotto[1], *C. Vanhulle*[2], *F. Chevallier-Hélas*[1], *L. Guyant-Maréchal*[1,3], *P. Saugier-Veber*[1,4], *C. Blondeau*[3], *T. Frebourg*[1,4], *P. Chambon*[1], *A. Goldenberg*[1];
[1]*Department of Genetics, Rouen University Hospital, Rouen, France,* [2]*Department of Neonatology, Rouen University Hospital, Rouen, France,* [3]*Department of Neurology, Rouen University Hospital, Rouen, France,* [4]*Inserm U1079, University of Rouen, Institute for Research and Innovation in Biomedicine, Rouen, France.*

SCN1A haploinsufficiency is associated with Dravet syndrome. We report a microdeletion involving SCN1A in a patient with profound handicap. After uneventfully first months of life, the proband presented at 4 months febrile seizures after a vaccination. Examination showed hypotonia and poor eye contact. In the following weeks, he presented recurrent febrile or afebrile seizures and his neurological status deteriorated with loss of eye contact, worsening hypotonia, stagnation of development. EEG, initially normal, were severely modified after several months. Epilepsy was refractory to drugs. Different types of seizures were reported : generalized, partial, myoclonic, absences, status epilepticus. Seizures were mostly provoked by slight hyperthermia. At 20 years, he was unable to sit without support, had no eye contact, expressed no words, had dysmorphic facial features, microcephaly. He underwent vertebral arthrodesis and gastrostomy. Array-CGH analysis identified a 3.2Mb de novo deletion at 2q24.3 involving SCN1A and 11 adjacent genes. The proband presented several criteria of Dravet syndrome : onset in the first year of life, frequent and intractable seizures of different types, febrile seizures, but his cognitive impairment was more severe than that commonly associated with this disease. 2q24.3 deletions are rare and mostly much larger and are associated with profound disability. The severity of the clinical presentation in this patient shows that haploinsufficiency of other genes on 2q24.3 contributes to the profound disability associated to 2q24.3 deletions. This observation shows that 2q24.3 deletions should be considered in patients presenting severe handicap associated with febrile seizures, a key feature of Dravet syndrome.

[1]*Kariminejad Najmabadi Pathology and Genetics Center, Shahrak Gharb, Tehran, Islamic Republic of Iran,* [2]*Tehran University of Medical Science, Tehran, Islamic Republic of Iran.*

A 6 years old girl with severe mental retardation was referred to our genetics lab. The first and only child of non- consanguineous healthy parents, she was delivered at age of 9 months by C-section. Her birth weight was 255 grams. At examination she does not walk or crawl. She had seizures when she was 2 months. Her facial features include epicanthal folds, puffiness of eyelids, strabismus, arched eyebrows, synophris, short upturned nose and long philtrum . She had notable hirsutism on her chin, forehead and legs.
Her karyotype was normal. Whole genome BAC Array Comparative Genomic Hybridization was performed using CYTOCHIP genomic BAC array version

3.0 and AGILENT 4x44 whole genome array. Data were analysed using BlueFuse Multi software. A 2.5 Mb deletion of 3p25.3p25.3 was detected.
The deletion spans nucleotides 8.85 Mb to 11.3 Mb covering 23 OMIM genes and 7 OMIM diseases. We compare phenotypic and genotypic findings of other overlapping cases. The deleted region in our patient includes the SRGAP3/MEGAP gene that has been formerly implicated in cognitive impairment in 3p microdeletion syndrome but does not include CAV3 gene.

P05.017
A pure de novo duplication of 9p in a woman with intellectual disability and dysmorphic features

A. Cieślikowska[1], *M. Kucharczyk*[1], *M. Kugaudo*[2], *M. Pelc*[1], *M. Krajewska-Walasek*[1], *K. Chrzanowska*[1];
[1]*Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland,* [2]*Department of Child and Adolescent Psychiatry, Medical University of Warsaw, Warsaw, Poland.*

Duplication of 9p is a fairly well-described syndrome. In spite of the variations in the size of the duplicated segment, its phenotype is clinically recognizable.
However, there are some reported cases with relatively mild phenotype, without intellectual disability. Due to phenotypic heterogeneity it is essential to present detailed phenotype description to delineate a critical region for the 9p duplication syndrome.
We report on a 20-year-old woman with pure de novo 9p duplication. She was referred to the genetic counseling unit because of intellectual disability and dysmorphic facial features. Moreover hypotonia in early childhood, short stature, scoliosis and hypergonadotropic hypogonadism were noted. The diagnosis of duplication was established by MLPA and delineated by arrayCGH as 46,XX.arr cgh 9p13.1-pter(199,254-38,751,949)x3 dn with the size of 38.55 Mb. Our report is one of the few ones giving the molecular and clinical characteristics of pure 9p duplication. In the literature there are some suggestions concerning the critical regions and phenotype-genotype correlation. However, the genes influencing the individual clinical manifestations of the 9p duplication have not yet been identified.
There is the need for further studies of 9p duplication patients to establish precise genotype-phenotype correlations in this chromosomal region.
The study was supported by MNiSW Grant No. 0605/B/P01/2009/37. Acquiring of the Roche NimbleGen microarray platform was co-financed by ERDF project (EU Structural Funds) POIG.02.01.00-14-059/09.

P05.018
Implementation of array comparative hybridization technology in detection of chromosomal abnormalities in patients with intellectual disability

G. Cardos[1], *V. Plaiasu*[2], *V. Celmare*[1], *D. Ochiana*[2], *G. Motei*[2], *M. Stoian*[1];
[1]*Personal Genetics-Medical Genetics Center, Bucharest, Romania,* [2]*Genetics Department - IOMC Prof.dr.Alfred Rusescu, Bucharest, Romania.*

Array Comparative Genomic Hybridization (aCGH) technology is a powerful tool for simultaneous detection of multiple chromosomal abnormalities with much higher resolution than conventional cytogenetics.
The aim of our study has been to implement the aCGH technology in detection of postnatal chromosomal abnormalities in patients with developmental delay/intellectual disabilities, with/without congenital anomalies (DD/ID/CA).
Seven patients with DD/ID/CA and dysmorphic features, aged between 1 to 14 years, previously assessed by conventional cytogenetic analysis, were included in aCGH analysis with NimbleGen ISCA Plus 3x1.4M Platform (Roche).
The aCGH analysis detected clinically relevant chromosomal abnormalities in three of the patients analyzed, with relevant abnormal phenotype.
For the first patient, the aCGH analysis precisely characterized the marker chromosome found by conventional cytogenetic analysis (karyotype: 46,XX der (8)), a duplication of 30 Mb being involved (8q13.3-q22.3 regions).
In the second patient case, a boy of 3 year old with DD/ID, obesity (karyotype: 46,XY,t(6;12)dn), the aCGH analysis identified a 6 Mb deletion on chromosome 6 (6q16.1-q16.2-q16.3 regions), with pathogenic significance.
In the third case patient, a boy aged 14 with DD/ID, facial dysmorphism and skeletal abnormalities (normal karyotype) a microduplication of 1.9 Mb in the 17p12-11.2 region was detected. This chromosomal region contains several important genes, including the dosage-sensitive RAI1 gene, suggesting the recently described Potocki-Lupski syndrome.
Our ongoing study demonstrates that aCGH is very useful in precisely identifying and characterizing chromosome anomalies (previously detected or not by conventional cytogenetics), being a valuable tool for providing an accurate diagnosis and helpful genetic counseling to the family.

Submicroscopic abnormalities in a girl with mental retardation and dysmorphic findings revealed by aCGH analysis

Y. K. Terzi[1], *F. I. Sahin*[1], *Z. Yilmaz Celik*[1], *I. Erol*[2];
[1]*Baskent University Faculty of Medicine Department of Medical Genetics, Ankara, Turkey,* [2]*Baskent University Faculty of Medicine Department of Pediatric Neurology, Ankara, Turkey.*

Specific copy number variations (CNVs) have been found to be associated with susceptibility to various intellectual and developmental disorders. One of those is mental retardation (MR) with developmental delay with an estimated prevalence of 2-3% in the general population. Application of array comparative genomic hybridization (aCGH) techniques to clinical practice, unraveled genetic aberration in MR patients with normal constitutional karyotype. Here we report a five-year-old girl with mental and motor retardation, epilepsy, and dysmorphic findings with normal constitutional karyotype. To determine the genetic contribution in the development of clinical findings, aCGH analysis was performed. Roche NimbleGen Human CGH ISCA Plus 3x1.4M Array was used for aCGH analysis. The data were analyzed by using Nexus6 software (BioDiscovery). As a result of aCGH analysis, 5 chromosomal regions were marked as important regions. Among these regions, one of them has been found to be related with autism spectrum disorder and intellectual disability, previously. Microdeletion in the *PTCHD1* locus on Xp22.11 has been has been found in autism spectrum patients but not in healty controls. However, we found a 24.3kb copy gain in the same locus in our patient. This finding showed that *PTCHD1* locus may not be disrupted with deletion only, copy gain in that region might also have effect on the gene, and its function. Also, other identified copy gains and loss may have contributed to the accompanying dysmorphic findings. As we experienced in the current patient, array CGH analysis is a valuable tool in uncovering submicroscopic chromosomal rearrangements.

Background: Allan-Herndon-Dudley Syndrome (AHDS) is typically characterized by severe psychomotor impairment. Mutations in the TH transporter gene, SLC16A2 (also known as MCT8) have been associated with the AHDS in more than 45 families. SLC16A2 is an essential TH transporter involved in the transport of TH across the blood-brain barrier and the blood-cerebrospinal fluid barrier.
Methods: We performed Agilent SureSelect enrichment of all X chromosome specific exons from the index patients, followed by massively parallel sequencing. All variants were filtered against the publicly available database.
Results: We identified a 5bp insertion in exon 3 of SLC16A2 gene in family D299, which likely caused a frameshift mutation (p.G334PfsX11). In family L107 we identified a C>A missense change (p.R445C) in exon 4. Both changes completely segregated with clinical phenotype in the families they were found and were not present in 100 anonymous Finnish controls. Affected patients in both families suffered from severe intellectual disability, impaired speech, poor head control & movement disorders.
Conclusions: The novel mutations in SLC16A2 confirm the diagnosis of Allan-Herndon-Dudley syndrome and represent, to the best of our knowledge, the first molecularly confirmed cases in the Finnish population.

Allan-Herndon-Dudley syndrome: increased serum triiodothyronine (T3) is a key diagnostic marker

A. Riess[1], *J. Kohlhase*[2], *U. Grasshoff*[3], *M. Schöning*[3], *O. H. Riess*[1], *A. Tzschach*[1];
[1]*Institute of Medical Genetics and Applied Genomics, Tuebingen, Germany,* [2]*Center for Human Genetics, Freiburg,, Germany,* [3]*Childrens Hospital, University of Tuebingen, Tuebingen, Germany.*

Allan-Herndon-Dudley syndrome (AHDS) is an X-linked intellectual disability syndrome caused by mutations in SLC16A2 which encodes the monocarboxylate thyroid hormone transporter 8 (MCT8). Clinically, the affected male patients are characterized by severe intellectual disability, initial hypotonia with subsequent spastic paraplegia, dystonic posturing and superimposed paroxysmal dyskinesia. The patients typically have elongated faces, but other dysmorphic features are less consistent. Leukodystrophy and white matter changes are present in early childhood and improve with age. The most specific laboratory finding in AHDS patients is an increase of serum triiodothyronine (T3), while serum thyroxine (T4) is decreased and thyroid-stimulating hormone (TSH) is either normal or mildly increased.
We report on a 17-year old patient with severe intellectual disability and neurological problems in whom increased serum T3 led us to suspect AHDS which was confirmed by the detection of a SLC16A2 mutation (c.812G>A, p.R271H).

Alstrom syndrome: two brothers with two heterozygous *ALMS1* mutations (Y1571X AND L1423X)

G. Pi[1], *J. Marshall*[2], *M. Ortiz*[1], ***A. Zuñiga***[1];
[1]*Hospital de la Ribera, Alzira (Valencia), Spain,* [2]*The Jackson Laboratory, Bar Harbor, ME, United States.*

Alstrom syndrome (AS, #203800) is a rare autosomal recessive disease characterized by multiorgan dysfunction. The key features are childhood obesity, blindness due to congenital retinal dystrophy, and sensorineural hearing loss. Associated endocrinologic features include hyperinsulinemia, early-onset type 2 diabetes, and hypertriglyceridemia. Thus, AS shares several features with the common metabolic syndrome, namely obesity, hyperinsulinemia, and hypertriglyceridemia. Mutations in the *ALMS1* gene have been found to be causative for AS. ALMS1 protein localizes to the basal bodies of cilia and plays an unknown role in intracellular trafficking.
CASE REPORT: We describe the case of two brothers of 13-year-old (male) and 11-year-old (female) born to unrelated healthy spanish parents. Both patients were attended in the Paediatric Service with a diagnosis of Alstrom syndrome. Boy had hypothyroidism, acanthosis nigricans and hepatosplenomegaly. He had normoacusia in the limit. The child also gave a history of photophobia with nystagmus along with 100% visual disability. The patient also had secondary metabolic myopathy which involved the proximal muscles and kyphosis. Girl had hypothyroidism, dyslipemia, hypoacusia and dilated caridomiopathy. As her brother, she was blind (100%) and had a history of photophobia with nistagmus. Both brothers had a progressive cronic nephropathy and central obesity. Genetic analysis showed that both were carriers of two heterozygous *ALMS1* mutations: c.5145T>G; p.Tyr1715X and c.4268T>A; p.Leu1423X. Both mutations cause a truncated protein and had been described previously in literature. Diagnosis of Alstrom Syndrome can be difficult because some features begin at birth and others emerge as the child develops and phenotype is family-dependent.

6q25.3 deletion encompassing ARID1B in a patient with intellectual disability and aggressive behavior

F. Lopes[1], *M. Barbosa*[2], *G. Soares*[2], *S. Sousa*[1], *T. Temudo*[3], *C. Gomes*[1], *P. Maciel*[1];
[1]*Life and Health Sciences Research Institute (ICVS), School of Health Sciences, University of Minho, Braga, Portugal,* [2]*Center for Medical Genetics Dr. Jacinto Magalhães, National Health Institute Dr Ricardo Jorge, Porto, Portugal,* [3]*Serviço de Pediatria, Hospital Geral de St. António, Porto, Portugal.*

Introduction
Intellectual disability (ID) is one of the most frequent and disabling neurological impairments in school-age children, accounting for 1-3% of the population in the developed countries. The impact of aCGH in the practice of Medical Genetics has been transformative, allowing genome-wide studies in patients with ID.
Patients and Methods
In this work we report a *de novo* deletion at 6q25.3 citoband in a patient with hirsutism, sparse and coarse hair, coarse face, bushy eyebrows, squint, bulbous nose, large mouth, thin upper lip, short stature, brachydactyly, umbilical hernia, borderline hepatosplenomegaly (on US).
The alteration was determined by aCGH analysis (Agilent 180K custom array) and the confirmation studies and inheritance analysis was carried out by qPCR using a fragment designed inside the altered region.
Results and conclusion
aCGH revealed a *de novo* 2.7 Mb deletion at chromosome region 6q25.3 containing 14 genes. This region was found to be deleted in patients with development delay, microcephaly, dysmorphic features and hearing loss together with sacral/anorectal malformations (Nagamani S. et al, 2009; Titomanlio L. et al, 2006). Among the genes affected in the patient, *ARID1B* (AT-RICH INTERACTION DOMAIN-CONTAINING PROTEIN 1B) was recently found to be mutated in Coffin-Siris syndrome patients. The authors also described copy number variations affecting *ARID1B* gene to be associated with the syndrome (Santem GW, et al, 2012). Siris syndrome and the intellectual and speech impairment also featured in the syndrome. Our patient brings new insight to the delineation of the 6q25 microdeletion syndrome and *ARID1B* haploinsufficiency in Coffin-Siris syndrome.

Chromosome Xq11.23 deletion of 846 kb in a 2,5-years old developmentally delayed boy with agammaglobulinemia

D. Ilencikova[1], *M. Hikkelova*[2], *A. Soltysova*[3], *Z. Kukova*[1], *A. Hlavata*[1], *L. Kovacs*[1];
[1]*II. Pediatric Department of Children University Hospital, Comenius University, Bratislava, Bratislava, Slovakia,* [2]*Gendiagnostica, Bratislava, Slovakia,* [3]*Laboratory of Genetics, Institute of Molecular Physiology and Genetics, Bratislava, Bratislava, Slovakia.*

We present a 2,5 years old male from orphanage, examined at the age of 11 months for developmental delay and frequent bronchitis. The boy is the first child of a healthy, consanguineous couple. His cousin died at the age of 3 years and was mentally retarded with immunodeficiency. He was delivered at 37 weeks of gestation, birth weight of 2700 g (pc=25th), length of 48 cm (pc=50th) with normocephaly. Clinical evaluation revealed: short stature (-4,2 SDS), hypotonia, hypotrophy, pectus excavatum, alopecia areata occipital, ventricular septal defect, congenital glaucoma, hypacusis mixta, CD19 negative agammaglobulinemia. Development milestones were delayed, he was lying in bed. For epilepsy and feeding problems we performed screening for metabolic disorders, but results were negative. Cerebral MRI was normal. The aCGH-chip 44 Oligo Microarray Agilent detected a deletion on chr X: 48.635.654-49.481.774 bp 846kb, Xp11.23. Fourty four genes are located in the deleted region including PQBP1 and SYP, which may be good candidates in generating the phenotype. The PQBP1caused Renpenning syndrome, an X-linked mental retardation syndrome with clinically recognizable features in our patient. The SYP is involved in regulation of gene for Wiskott-Aldrich syndrome.

Array-CGH study of chromosomal rearrangements in patients with intellectual disability from Russia and Ukraine

N. V. Hryshchenko[1], *N. A. Skryabin*[2], *A. A. Kashevarova*[2], *L. A. Livshits*[1], *I. N. Lebedev*[2];
[1]*Institute of Molecular Biology and Genetics NAS of Ukraine, Kyiv, Ukraine,* [2]*Institute of Medical Genetics, Tomsk, Russian Federation.*

This research is an extension of the chromosomal rearrangements study in patients with intellectual disability (ID), which was supported by EC FP-7 CHERISH project (no. 223692). The previously obtained results based on array-CGH screening revealed pathogenic causative CNVs in 15.8% of patients with ID (9 of 57). Thereby the high information content of array-CGH for identification of genomic rearrangements associated with ID has been proved. As far as the majority of identified chromosomal deletions and duplications were benign (non-pathogenic) CNVs, it is important to distinguish common CNVs in the observed groups. Therefore we initiated a molecular cytogenetic study in ID-patients of two similar ethnic groups (Slavic Russian and Ukrainian populations).
The first data of array CGH analysis showed that the most frequent CNVs in our groups were dup8p11.23-p11.22, dup/del15q11.2 and dup6p21.32.

The high frequency of these rearrangements suggests that they are benign, but this hypothesis needs to be verified. In contrast, rare probably pathogenic chromosomal rearrangements have been also detected in both groups of patients, some of which are identical in patients from Russia and Ukraine.
Further research will allow us to define the role of novel CNVs in the ID-phenotype manifestation, and determine the frequency of common pathogenic as well as non-pathogenic rearrangements in both populations.
The results of this study will significantly improve information content of molecular cytogenetic screening based on array-CGH in ID-patients from our countries.

A small de novo 16q24.1 duplication in a woman with severe clinical features

S. Redon[1,2], *C. Bénech*[3,1], *S. Audebert-Bellanger*[2], *G. Friocourt*[1], *M. Planes*[2], *P. Parent*[2], *C. Férec*[1,2,3];
[1]*INSERM U1078, Brest, France,* [2]*CHRU, Brest, France,* [3]*EFS, Brest, France.*

We report here a de novo 16q24.1 interstitial duplication in a woman with a severe phenotype consistent with mental retardation, spastic paraplegia, severe epilepsy, a narrow and arched palate, malar hypoplasia, little subcutaneous fat and arachnodactyly. Although conventional karyotyping was found to be normal, array-CGH detected a small duplication on chromosome 16. Using QFM-PCR, we characterised its proximal and distal breakpoints. The duplication, which is approximately 250 kb, encompasses seven genes (KIAA0182, GINS2, c16orf74, COX4NB, COX4I1, MIR1910 and IRF8). Several reports have previously described large 16q duplications, and some of these overlap with our region in 16q24.1.
Due to the variability of the described phenotypes, the characterisation of small 16q duplications may help to determine critical regions and the genes they contain that are associated with the components of complex phenotypes.

CHU de Strasbourg - Nouvel Hôpital Civil, Strasbourg, France,* [10]*Service de radiopédiatrie, hopital Robert Debré, Paris, France.*

Primary recessive microcephaly (MCPH) caused by ASPM mutations is a model of abnormal brain development linked to neural progenitors proliferation defects. MCPH is defined as a homogenous reduction of cerebral volume principally affecting the cortex. The reduction of brain volume has been correlated to cognitive disabilities. However, correlation between cognitive functions and structural brain phenotype has not yet been well established in genetic microcephalies.
Here, we provide evidence that specific cognitive functions are preserved in ASPM-related patients and this is correlated with their structural brain changes. General intelligence, memory scales and structural brain magnetic resonance imaging scans were acquired from 6 ASPM-related patients.
Using cranial MRI, we measured the volume of the different brain structures and focused on the analyze of the cortical volume, surface and thickness. These microcephalic patients have a normal mnesic functioning and preserved hippocampal volume compared to other cortical areas.
Unlike most previous data that linked microcephaly to mental retardation, these findings suggest i) that these microcephalic ASPM-related patients are able to learn despite their cognitive disabilities and ii) that other master genes than ASPM are necessary for the development of hippocampus formation and function.

P05.029
ATRX duplication syndrome: two overlapping duplications at Xq13.3-q21.1

F. Martinez, *M. Rosello, S. Mayo, S. Monfort, S. J. Oltra, C. Orellana;*
Fundacion para la Investigacion, Valencia, Spain.

In two unrelated male patients with syndromic intellectual disability (ID) we detected two duplications of 12 and 18 Mb, respectively, by array-CGH. The common overlapping interval spans 6Mb at Xq13.3-q21.1, where only 25 genes are annotated. Interestingly, both patients also share many clinical features, suggesting a major role for any of the genes contained in the common interval. Among these, the most outstanding is ATRX, the causative gene of X-linked alpha-thalassemia/mental retardation syndrome, one of the growing list of genes implied in chromatin remodeling causing ID: MECP2, CBP, RSK2, NSD1, etc. Many of these genes, especially MECP2, which closely interacts with ATRX, are dose-sensitive so that not only haploinsufficiency mutations, but also duplications are related with syndromic ID.
Among the clinical features, both patients share severe ID, absent expressive speech, early hypotonia, behavioral problems (hyperactivity, repetitive self-stimulatory behavior), postnatal growth deficiency,microcephaly,micrognathia, cryptorchidism and several dysmorphic features such as low-set posteriorly rotated ears or downslanting palpebral fissures. These features strikingly resemble the usual findings among patients with loss-of-function mutations of this gene. Furthermore, only one of the carrier mothers of our patients was informative in the analysis of X-chromosome inactivation, and she showed a completely skewed X-chromosome inactivation. This is a constant finding among female carriers of inactivating point mutations of this gene. Taken all together, although the implication of further genes cannot be excluded, we propose that the increased dosage of ATRX is the major pathogenic mechanism of this X-linked phenotype, a duplication syndrome that evokes that of MECP2.

Custom designed CGH array in autism spectrum disorders

C. Orellana, *M. Roselló, S. Monfort, S. Mayo, S. Oltra, F. Martinez;*
Hospital Universitario La Fe, Valencia, Spain.

Introduction: Autism spectrum disorders (ASD) have a complex multifactorial etiology. Recently, copy number variants (CNV's) have been shown to contribute to over 10% of ASD cases. Many of the known genes whose mutations cause ASD, have functions related to epigenetic regulation. We have applied a custom-designed oligo array CGH with an exonic overlapping coverage of 450 genes known to cause autism or intellectual disability and autism candidate genes related to epigenetic machinery.
Material and methods: Custom oligonucleotide arrays (formats 4x44 and 8x60) were designed with e-Array Agilent technology. The final array design contains: 36,000 exonic probes for 450 genes considered of high priority (mean distance between probes 25bp), 2,000 probes for regulatory elements and microRNA's and 22,000 whole genome probes (backbone).
Results: We have studied a series of 139 patients including syndromic autism and/or familial cases of idiopathic autism. We have found 24 cases with pathological CNV's. Most are non-recurrent CNV, what allow us to propose new candidate genes involved in autism.
Discussion: Our results confirm the importance of three regions in autism: Xq28 (MECP2), 22q13 (SHANK3) and 16q13, while all others regions are extremely heterogeneous. Most pathological CNV were found in cases with syndromic autism.

P05.031
The 15q11.2 deletion and autism spectrum disorders

V. De Wolf, *H. Peeters, K. Devriendt;*
KU Leuven, Leuven, Belgium.

Autism Spectrum Disorders (ASDs) are frequent genetic neurodevelopmental disorders. Several studies have shown the association of Copy Number Variations, both *de novo* and rare inherited, with ASD. Deletions of chromosome 15q11.2 (BP1-BP2 region) including *CYFIP1, NIPA1, NIPA2* and *TUBGCP5*, are associated with intellectual disability, epilepsy, schizophrenia and autism. *CYFIP1* is an important binding partner of FMRP and *FMR1* mutations cause Fragile X syndrome, often associated with autism (30%). Also, patients with the Prader-Willi phenotype caused by paternal deletions of the 15q11-13 BP1-BP3 region present a more severe behavioral phenotype

(ADHD, autism and OCD) compared to those having the BP2-BP3 deletion. Together, this pinpoints the 15q11.2 deleted region as a risk variant for ASD.
Quantitative Real-Time Polymerase Chain Reaction is used to test the occurrence of deletions of *CYFIP1* in ASD patients with intellectual disability (IQ<70), ASD patients with normal intelligence (IQ>70) and controls. We also performed exome sequencing on two ASD families with the proband carrying the del15q11.2, inherited from a normal parent.
We present the results of an association study of *CYFIP1* deletions in ASD patients. Given the variability of the phenotype of del15q11.2, we hypothesize that additional variants in the other allele, genes of the FMRP network or known ASD genes can contribute to the phenotype (multi-hit model). We present the results of exome sequencing of two ASD families, searching for additional hits.
The 15q11.2 deletion is likely to be a risk factor for ASD with/without mental retardation. A multi-hit model could explain the phenotypic variability.

V. De Wolf: None. **H. Peeters:** None. **K. Devriendt:** None.

P05.032
The genetic basis of autism spectrum disorders: identification and analysis of structural variants

N. Brison[1], *S. Iqbal*[1], *W. De la Marche*[2], *J. Steyaert*[2], *I. Noens*[3], *K. Devriendt*[1], *H. Peeters*[1];
[1]*Department of Human Genetics, K.U.Leuven, Leuven, Belgium,* [2]*Department of Adolescent and Child Psychiatry, K.U.Leuven, Leuven, Belgium,* [3]*Department of Parenting and Special Education, K.U.Leuven, K.U.Leuven, Leuven, Belgium.*

Background:
The genetic causes of autism spectrum disorders (ASDs) are heterogeneous and still unknown in the majority of cases. Structural copy number variants (CNVs) were found in sufficiently high frequency to suggest that cytogenetic and microarray analyses are considered in routine clinical workup. An interesting paradigm for clinical practice is that each rare CNV may account for only a small proportion of variance in ASD at the population level but may have a large effect in a few families in which it segregates.
Material and methods:
CNV association studies are performed in a family based cohort. The sample contains 161 families ascertained through one or more autistic probands with normal intelligence or mild intellectual disability. The study cohort contains 648 individuals: 227 probands, 324 parents, 97 unaffected siblings belonging to 161 families. All probands, unaffected siblings and parents are genotyped with high-resolution Illumina OMNI 2.5-8v1 microarrays. For all individuals, an extensive list of phenotypic information is collected including IQ, SRS scores, 3DI, clinical genetic examination and family history.
Results:
We present the results of a family based study on the validity of CNV detection in ASD using a high resolution platform. We study the segregation of known and novel rare CNVs with qualitative and quantitative autism phenotypes. Additionally association studies are performed with respect to amongst others gene content and parental origin.
Conclusion:
With this study we aim to contribute to the clinical validation of the current knowledge of ASD risk variants and to the identification of novel variants.

P05.033
New role for microtubule plus-end tracking proteins: mutation in the CLIP-1 (CLIP-170) gene causes autosomal recessive intellectual disability (ARID)

F. Larti[1], *K. Kahrizi*[1], *L. Musante*[2], *H. Hu*[2], *T. Wienker*[2], *M. Banan*[1], *Z. Fattahi*[1], *N. Bazzazadegan*[1], *Z. Liu*[3], *E. Papari*[1], *H. Ropers*[2], *N. Galjart*[3], *H. Najmabadi*[1];
[1]*Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran,* [2]*Department of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Berlin, Germany,* [3]*Department of Cell Biology and Genetics, Erasmus MC, Rotterdam, Netherlands.*

In the context of a comprehensive research project, investigating novel ARID genes, linkage analysis based on autozygosity mapping helped us to identify a new ID locus on Chr.12q24.13-q24.31 (LOD =3.7), in an Iranian family. Next generation sequencing following exon enrichment in this genomic interval, detected one nonsense mutation (p.Q1010X) in the *CLIP-1* gene. This gene encodes a member of microtubule plus-end tracking proteins that specifically associates with the ends of growing microtubules. CLIP-170 contributes to kinetochore–microtubule attachments, and has a role in neuronal development. It is also necessary for axon formation and dendrite morphology in rat neurons. The detected mutation completely removes part of the central α-helical coiled coil domain and the two functional C-terminal metal-binding motifs, disturbing CLIP-170 intramolecular conformational changes and its interaction with other proteins. In order to prove the involvement of *CLIP-1* in neurodevelopmental disorders, we studied mutant and normal established lymphoblastoid and skin fibroblast cell lines. Reverse transcriptase PCR confirmed the stop codon in all of the mutant cell lines. Western blotting with antibodies against the N-terminus of CLIP-170 revealed a truncated protein in affected individuals' cell lines; while a C-terminal-specific antibody didn't detect any protein. Immunofluorescence microscopy experiments confirmed the Western blot data, showing microtubule plus-end staining in wild type and mutant *CLIP-1* fibroblasts with N-terminal-specific antibodies, whereas C-terminal-specific CLIP-170 antibody just showed staining in normal fibroblasts. Altogether, our data present the first evidence for the involvement of the CLIP-170 in cognitive function and we propose *CLIP-1(CLIP-170)* as a novel gene for ARID.

De Novo Intragenic Deletion of *AUTS2* in a Patient with Developmental Delay: A Case Report

L. K. McGregor[1], *A. Jolley*[2], *W. Waters*[2], *S. Brown*[2], *J. Nicholl*[2], *S. Yu*[2,3];
[1]*South Australian Clinical Genetics Service, Directorate of Genetics and Molecular Pathology, SA Pathology at Women's and Children's Hospital, South Australia, Adelaide, Australia,* [2]*Department of Genetic Medicine, Directorate of Genetics and Molecular Pathology, SA Pathology at Women's and Children's Hospital, South Australia, Adelaide, Australia,* [3]*School of Paediatrics and Reproductive Health, The University of Adelaide, Adelaide, Australia.*

Array CGH identified a de novo interstitial deletion of 683-806kb at chromosome 7q11.22 involving multiple exons of the *AUTS2* gene, in a 13 year old male with learning difficulties, developmental delay, short stature, ptosis and facial dysmorphism. This is the second report of an isolated *de novo* intragenic deletion of *AUTS2.*
The proband was referred with a history of proportionate short stature, hypotonia, delay in speech and fine motor skills, ptosis and facial dysmorphism. Array CGH was performed using the BlueGnome Cytochip oligo ISCA 8 x 60K array platform. Array CGH revealed a *de novo* interstitial deletion at chromosome 7q11.22 involving exons 3 - 5 of *AUTS2* and no other copy number variants. His parents and unaffected brother had no deletion.
The *AUTS2* gene spans 1.19Mb of genomic DNA on chromosome 7 contains 19 exons. The molecular function of *AUTS2* is unknown. Previous publications describe a number of individuals with disruptions involving *AUTS2* who present with developmental delay/ intellectual disability, hypotonia and autism. Early cases all resulted from translocations or inversions which disrupted other genes in addition to *AUTS2* and made it difficult to attribute the phenotype to *AUTS2* alone. The patient described in our report (and a recent report of another two patients) who have intragenic deletions of AUTS2 with no other CNVs provides strong evidence that disruption of *AUTS2* alone results in a syndromic neurodevelopmental disorder.

P05.035
A comprehensive study on Iranian patients with Bardet-Biedl syndrome

Z. Fattahi[1,2], *P. Rostami*[2], *A. Najmabadi*[3], *M. R. Akbari*[4], *A. Kariminejad*[2];
[1]*Genetics Research Centre, University of Social Welfare and Rehabilitation Sciences, Tehran, Islamic Republic of Iran,* [2]*Kariminejad - Najmabadi Pathology & Genetics Center, Tehran, Islamic Republic of Iran,* [3]*University of California,San Diego, San Diego, CA, United States,* [4]*Women's College Research Institute, University of Toronto, Toronto, ON, Canada.*

Bardet-Biedl syndrome (BBS) is a rare genetic disorder affecting brain with a wide range of phenotypes, including deterioration of the intellect and neurological functions. BBS is a heterogeneous disorder, typically inherited in an autosomal recessive manner with 16 known genes.
This study was performed to detect responsible genes and mutation spectrum in a cohort of 23 Iranian BBS patients. Initially, the most commonly mutated genes (BBS1, BBS2 and BBS10) accounting for about 50% of BBS patients were screened by direct Sanger sequencing. Final diagnosis was determined for 4 patients in BBS2 gene, including three novel mutations. Next, three of the remaining patients were chosen and whole exome sequencing

was performed. Coverage of known BBS genes was 97% in average at 20x depth of coverage. Whole exome sequencing revealed novel BBS4 mutation in one patient, and other two patients had no mutations in any of the 16 known BBS genes. Finally, six other commonly mutated BBS genes (BBS3, BBS4, BBS6, BBS7, BBS9 and BBS12) accounting about 20% of BBS patients, were selected for screening in the remaining 16 patients, which is currently underway. However, responsible mutations have been identified for 5 other patients in BBS12 and BBS9 genes, including three novel mutations.
Our result shows that despite the reported high prevalence of BBS1 and BBS10 mutations in BBS patients of other populations, these two genes may not play an important role in Iranian patients whilst other genes like BBS2 and BBS12 seem to have a greater role comparing to other populations.

P05.036
Diagnosis and management of Bohring-Opitz Syndrome with or without ASXL1 mutations

J. M. Graham[1], *B. Russell*[2], *J. Johnston*[3], *L. Biesecker*[3];
[1]*Cedars Sinai Medical Center, Los Angeles, CA, United States,* [2]*UCI Medical Center, Los Angeles, CA, United States,* [3]*National Human Genome Research Institute NIH, Bethesda, MD, United States.*

We define the characteristic features and management for Bohring-Opitz Syndrome (BOS), a rare genetic condition characterized by distinctive facial features, characteristic posture, microcephaly, severe intellectual disability and feeding problems. Since being initially delineated in 1999, there are now approximately 30 published cases. In 2011, Hoischen *et al.* identified *de novo* nonsense mutations in *ASXL1* in 7 out of 13 patients with BOS. Previously, somatic mutations in *ASXL1* have been detected in myeloid malignancies, suggesting *ASXL1* might be involved in tumor suppression. We report natural history from 3 previously unpublished patients with BOS, including the first known case of BOS with bilateral Wilms tumors. All 3 patients had novel *de novo* frameshift mutations in *ASXL1*, and 2 patients are normocephalic with varied feeding issues and distinctive personalities (interactive, happy, and curious). Surviving patients with BOS may have a risk for tumors, and 2 previous patients with BOS had neoplasms. One patient with BOS died at 5 months with bilateral nephroblastomatosis, and another patient with BOS developed medulloblastoma at age 5 years; neither had mutations in *ASXL1*. With a malignancy potential for BOS, tumor surveillance should be considered in patients with and without *ASXL1* mutations for disease monitoring and management. Diagnostic criteria may also need to be broadened to help identify previously undiagnosed cases. We review these 3 new cases and compare them with previous cases of BOS with and without mutations in *ASXL1,* and also with patients with mutations in *ASXL3,* to broaden diagnostic criteria and suggest a tumor surveillance protocol.

Phenotype of the french cohort of Börjeson-Forssman-Lehmann syndrome

I. Marey[1], *R. Touraine*[2], *F. Prieur*[2], *A. Toutain*[3], *S. Blesson*[3], *M. Raynaud*[4], *P. Edery*[5], *J. Roume*[6], *V. Des Portes*[7], *D. Héron*[1];
[1]*Groupe Hospitalier Pitié Salpetriere, paris, France,* [2]*Service de Génétique,Centre Hospitalier Universitaire, Saint Etienne, France,* [3]*Service de génétique médicale, Centre hospitalier Universitaire, Tours, France,* [4]*Laboratoire de génétique moléculaire, Centre hospitalier Universitaire, Tours, France,* [5]*Service de génétique clinique, Centre hospitalier Universitaire, Lyon, France,* [6]*Service de génétique médicale, Centre hospitalier Intercommunal de Poissy, Poissy, France,* [7]*Service de neurologie pédiatrique, Centre hospitalier Universitaire Lyon, Lyon, France.*

Börjeson-Forssman-Lehmann syndrome (BFLS) is an X-linked mental retardation syndrome first described in 1962. It is characterized by the association of intellectual disability, epilepsy, microcephaly, short stature and obesity, hypogonadism and characteristic craniofacial features. Some heterozygous females have mild clinical manifestations of BFLS.
BFLS is caused by mutations in the gene PHF6 whose function is unknown. The encoded protein might play a role in chromatin remodeling, in transcriptional regulation, cell growth and proliferation.
In a National Clinical Research Project on Intellectual Disabilities linked to the X chromosome, we gathered the medical records of 8 french male patients with a mutation in PHF6 gene and 7 female carriers within 5 families.
In males, intellectual disability, ranging from moderate to severe, characteristic craniofacial morphology, obesity, gynecomastia and hypogonadism were constant fetaures. Deafness and hypothyroidism were two frequent features in our cohort, whilst microcephaly and short stature were less frequent.
Three female carriers with random X-inactivation were symptomatic, with one of them having mild intellectual disability and the other two harboring suggestive craniofacial dysmorphism. Three asymptomatic female carriers had a skewed X-inactivation. Thus, X-inactivation, whether random or skewed, may determine the presence or the absence of mild signs of BFLS in female carriers.
At the molecular level, two PHF6 mutations had been previously reported and three were novel missense mutations. On the whole, 17 different PHF6 mutations were identified in BFLS patients.
Our data are in line with those of the BFLS literature. This ongoing study will focus on neuropsychological phenotyping of BFLS patients.

The genetic causes of malformations of cortical development (MCD) remain largely unknown. Here we report the discovery of multiple disease-causing missense mutations in TUBG1, DYNC1H1 and KIF2A, as well as a single germline mosaic mutation in KIF5C. We find a frequent recurrence of mutations in DYNC1H1, implying that this gene is a major locus implicated in unexplained MCD. The mutations in KIF5C, KIF2A and DYNC1H1 drastically affect ATP hydrolysis, productive protein folding or microtubule binding, while suppression of Tubg1 expression in vivo interferes with proper neuronal migration and expression of Tubg1 mutations in S. cerevisiae results in disruption of normal microtubule behaviour. Our data reinforce the importance of centrosome- and MT-related proteins in cortical development and strongly suggest that MTdependent mitotic and post-mitotic processes are major contributors to the pathogenesis of MCD.

Prospective Study of Functional Outcomes in Children with Cerebellar Atrophy

A. Al-Maawali, *S. Blaser, X. Zhao, G. Yoon;*
The Hospital for Sick Children, Toronto, ON, Canada.

AIM: To identify clinical and radiological predictors of functional outcome in patients with childhood onset cerebellar atrophy.
METHODS: Over a period of 5 years, we evaluated 44 patients with confirmed cerebellar atrophy on MRI. Patients were grouped according to whether the cerebellar atrophy was isolated or associated with other radiological abnormalities. Patients with posterior fossa malformations or non-genetic

aetiologies of cerebellar atrophy were excluded. MRI (1.5 T) was carried out 73 times on 44 patients. The severity of cerebellar atrophy using qualitative and quantitative scoring systems was recorded. Standardized activities of daily living (ADL) assessment was used to characterize the spectrum of functional outcomes. The characteristics of the participants were analyzed using descriptive statistics.

RESULTS: We evaluated 44 patients, 26 male and 19 female. The mean age of symptom onset was 20 months (range, birth to 10 years). The isolated cerebellar atrophy group had better functional outcomes compared to those with cerebellar atrophy associated with other radiological abnormalities. Age of onset of cerebellar atrophy before 2 years of age, progression of cerebellar atrophy on MRI, presence of seizures, and decreased size of transverse cerebellar hemisphere diameter were associated with worse functional outcomes.

CONCLUSIONS: We present a prospective study of clinical and radiological predictors of functional outcome in patients with childhood onset cerebellar atrophy. This information may be useful in the diagnosis and future management of this complex group of disorders.

P05.040

A new family with *SLC9A6* mutation expanding the phenotypic spectrum of Christianson syndrome

A. Masurel-Paulet[1], *A. Piton*[2], *S. Chancenotte*[3], *C. Redin*[2], *D. Minot*[1], *A. Creppy*[2,4], *M. Ruffier-Bourdet*[3], *C. Thauvin*[1,5], *J. Thevenon*[1,5], *A. Curie*[6], *G. Blanchard*[6], *M. Bonnet*[3], *M. Archimbaud*[3], *J. Mandel*[2,4], *L. Faivre*[1,5];

[1]*Centre de génétique et Centre de Référence Anomalies du développement et Syndromes malformatifs, CHU DIJON, France,* [2]*Department of Neurogenetics and Translational medicine, IGBMC, CNRS/INSERM and University of Strasbourg, Illkirch, France,* [3]*Centre Référent des Troubles du Langage et des Apprentissages, Hôpital d'Enfants, CHU DIJON, France,* [4]*Laboratoire de Diagnostic génétique, CHU Strasbourg, France,* [5]*EA 4271 GAD, Faculté de Médecine, Université de Bourgogne, Dijon, France,* [6]*Service de Neurologie Pédiatrique, CHU Lyon, Hôpital Femme Mère Enfant, Bron, France.*

High-throughput sequencing can broaden the clinical variability associated to a known gene, by sequencing panels of genes in patients with no precise clinical diagnosis. From a series of 50 patients with undiagnosed ID studied by targeted sequencing of 220 ID-genes, we identified a splicing mutation (c.526-9_526-5del) in the *SLC9A6* gene in a 9-year-old boy with mild ID, microcephaly and social interaction disabilities. This intronic microdeletion leads to skipping of exon 3 and to an inframe deletion of 26 aminoacids in the TM4 domain. It segregates with cognitive impairment or learning difficulties in other members of the family. Mutations in *SLC9A6* have been reported in X-linked Christianson syndrome associating severe to profound intellectual deficiency and an Angelman-like phenotype, with microcephaly, absent speech, ataxia with progressive cerebellar atrophy, ophtalmoplegia, epilepsy, and neurologic regression. Interestingly, the proband and his maternal uncle have an attenuated phenotype with mild intellectual disability, attention deficit disorder, speech difficulties, microcephaly and mild asymptomatic cerebellar atrophy. The mutation cosegregated with learning disabilities and speech difficulties in the carrier females (mother and 3 sisters of the proband). Detailed neuropsychological, speech and occupational therapy investigations revealed a disorder of oral and written language acquisition, with dissociation between verbal and performance IQ. An abnormal phenotype has been described previously in a large proportion of carrier females, ranging from learning disability with predominant speech difficulties to mild intellectual deficiency. In conclusion, besides broadening the clinical variability of *SLC9A6* gene mutations, we show an example of a monogenic origin of mild learning disability.

A Novel 0.34 Mb Microduplication of 9q34.3 in a Patient with a Congenital cardiac defects and Learning Disabilities

M. Saleh[1], *S. Horsburgh*[2,3], *M. Shago*[1], ***H. Faghfoury***[2,3];

[1]*The Hospital for Sick Children, Toronto, ON, Canada,* [2]*Mount Sinai Hospital, Toronto, ON, Canada,* [3]*University Health Network, Toronto, ON, Canada.*

We report a 19- year-old male with a learning disability and congenital heart defects. The patient also had mild dysmorphic features including facial asymmetry and mid-facial hypoplasia, high-arched palate with dental crowding. Chromosomal microarray analysis demonstrated a 0.34 Mb duplication on 9q34.3, confirmed by Fluorescence in situ Hybridization (FISH). The 9q34.3 duplication we report is the smallest duplication among the cases reported thus far and includes the genes EHMT1 and NELF. The clinical manifestations in our patient were similar to those described in other reported cases of larger 9q34 duplications, implying that our small duplication encompasses a critical region for brain, cardiac and craniofacial development. We also compare our patient with its 9q34 deletion counterpart, Kleefstra syndrome, and demonstrate the overlap between the two conditions.

P05.042

Familial supernumerary chromosome composed of centromeric and pericentromeric regions of chromosome 8 cosegregating with intellectual disability and psychiatric disorder

P. Blanchet[1], *J. Puechberty*[1], *G. Lefort*[2], *D. Cunz-Shadfar*[3], *C. Baeza Velasco*[1], *L. Pinson*[1], *C. Coubes*[1], *J. Chiesa*[4], *S. Taviaux*[2], *D. Geneviève*[1], *M. Willems*[1];

[1]*Département de Génétique Médicale, Hôpital Arnaud de Villeneuve, Montpellier, France,* [2]*Département de Cytogénétique, Hôpital Arnaud de Villeneuve, Montpellier, France,* [3]*Département de Neuropédiatrie, Hôpital Gui de Chauliac, Montpellier, France,* [4]*Département de Cytogénétique, Hôpital Caremeau, Nîmes, France.*

We describe three generations of a family showing perfect cosegregation of intellectual disability and psychiatric disorder with a small pericentromeric chromosome 8-derived supernumerary chromosome. Two sisters aged 3 and 7 years were referred to our Genetics Department for delayed psychomotor development, intellectual disability, behaviour disorder and autistic spectrum disorder without associated dysmorphism or malformation. They are the first and third born from unrelated parents. Their mother had learning difficulties in her youth and as an adult suffers from psychiatric disorder as well as severe depression and inadequate social behaviour. Their maternal grand-mother presented the same features, with alcohol and benzodiazepin dependence in addition. Molecular investigation for Fragile-X and Steinert's disease, as well as metabolic screening and cerebral MRI, revealed no anomaly. All 4 have a small supernumerary chromosome, discovered on standard blood chromosome analysis. Fluorescence in situ hybridization identified the marker as derived from the centromeric and pericentromeric regions of chromosome 8. Comparative genomic hybridization array (25kb-resolution) confirmed a 9.1Mb partial trisomy for chromosome 8; The karyotype is: 47,XX,+der(8)(p11.2q11.21).

The two maternal half-sisters of the mother and the sister of the two children, who don't carry the chromosomal anomaly, have neither ID nor psychiatric disturbance. There is little concerning this chromosomal anomaly in the literature. Only two patients have been reported, with psychomotor retardation or mild intellectual disability. It is our opinion that that this supernumerary chromosome is responsible for a phenotype associating intellectual disability and psychiatric disorder without specific facial features nor malformation.

P05.043

The first familial case with the entire *CNKSR2* gene deletion corroborating its involvement in X-linked intellectual disability and Attention-Deficit/Hyperactivity Disorder (ADHD)

R. HARBUZ, *F. BILAN, D. COUET, P. DUMAINE, A. KITZIS, B. GILBERT-DUSSARDIER;*

Service de génétique, CHU de Poitiers, Poitiers, France.

CNKSR2 (Connector enhancer of Kinase Suppressor of Ras 2) is exclusively expressed in adult and fetal brain and encodes CNK2, a protein involved in signal transduction in mitogen-activated protein kinase (MAPK) pathway downstream from RAS. Until now, this gene has been reported as causing non syndromic intellectual disability only in one sporadic case (*Houge et al. Mol Syndromol. 2012*). We could see two brothers (age of 10 and 11 at the moment of investigation) with delayed psychomotor development (they could seat at 8-9 months and walk at 2 years of age), with especially severe ADHD and speech delay. Furthermore, the youngest brother developed epilepsy. Physical examination did not show any dysmorphic feature, but both brothers present flat and large feet and mild joint hyperlaxity. Whole genome oligonucleotide microarray CGH 105K (Agilent Technologies, Inc. Santa Clara, USA) revealed in both brothers a maternally inherited 513 kb deletion on Xp22.12, which removed the entire sequence of *CNKSR2*. This is the second observation of CNV affecting this gene inherited from unaffected carrier mother, and the first familial case. In the previous case, a 234-kb deletion, removing the major part of *CNKSR2*, was observed. The main clinical features in published and present cases are: developmental delay, especially

speech delay, ADHD and epilepsy. Until now, no point mutation in this gene has been reported. We suggest that the *CNKSR2* gene would be analyzed in male patients with non syndromic intellectual deficiency, when associated with severe ADHD, once the fragile X syndrome has been excluded.

P05.044

Exome sequencing identifies a novel mutation in X-chromosomal gene in brothers with congenital hypothyreosis, short stature and mental retardation

S. Kivirikko[1], *E. Salminen*[1], *S. Vanhanen*[2], *K. Aittomäki*[1];
[1]*Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland,* [2]*Department of Pediatric Neurology, Hyvinkää Hospital, Hyvinkää, Finland.*

The proband is the 3rd child of healthy non-consanguineous Finnish parents. During pregnancy polyhydramnion was noted. Birth measurements were 2982 g/ 48 cm/ 34 cm. The older brother of the proband was diagnosed with congenital hypothyroidism at the age of 6 months, with epilepsy at 3 years of age. He is moderately mentally retarded. His height was 88,1 cm (-2.1 SD) at the age of 3 years. The 2nd child of this family is a healthy girl.
Muscle hypertonia was noted when the proband was 3 months old. Hypothyroidism was diagnosed when he was 6 months old and around the same time his growth started to lag. Proband's height is 95,5 cm (-2.6 SD). He developed his first seizures at age 1 year and 2 months. His global development has been moderately delayed. At the age of 4 years and 3 months he walks independently, but is not able to speak.
The chromosomes (400 bands) and aCGH (44K) were studied because of short stature and mental retardation. Both of these results were normal. Because the family history fitted X-chromosomal inheritance and clinical findings resembled Allan-Herndon-Dudley, MCT8 gene was analysed with normal results. Exome sequencing (NimbleGen SeqCap EZ Human Exome Library v2.0) identified a novel 3 bp deletion in a X-chromosomal gene causing a known syndrome. Affected boys were hemizygous and their mother is a carrier of the mutation. The mother is healthy, but her height is 150 cm (-2.5 SD).

Complex cortical malformations associated with mutations in tubulin genes TUBA1A, TUBB2B, TUBB3 and TUBB5, commonly referred to as « Tubulinopathies », are a heterogeneous group of conditions which include a wide spectrum of clinical severity. Of the 125 patients selected as having complex cortical malformations, 41 (32.8%) were found to carry TUBA1A, 18 (14.4%) TUBB2B mutations, 11 (8.8%) TUBB3 and 3 (2.4%) TUBB5 mutations. Here, we describe their occurrence together as the two major findings in a group of at least five cortical malformation syndromes: (i) lissencephaly (16) (ii) microlissencephaly (10), (iii) central pachygyria (13), (iv) polymicrogyria-like cortical dysplasia either diffuse (6), central (11) or multifocal (10) and (v) simplified gyral subtype (7). Dysmorphic basal ganglia (45; 61.6%) are hallmark of tubulinopathies more visible in central pachygyria, polymicrogyria, and simplified gyral malformations. Tubulinopathies are also characterized by a high prevalence of corpus callosum agenesis (35.6%), and mild to severe cerebellar hypoplasia and dysplasia (79.4%). Foetal cases (23) represent the severe end of the spectrum and show specific abnormalities (i.e. enlarged germinative zones, neuronal heterotopia and disorganised corticospinal tracts) that provide insights in the understanding of pathophysiology.
Overlapping phenotypes may exist between tubulinopathies. TUBA1A mutations account for lissencephaly (15 ; 93.7%), central pachygyria (13 ; 100%), microlissencephaly (7 ; 70%), but less frequently for PMG (6 ; 22%). By contrast, β-tubulin (TUBB2B, TUBB3B and TUBB5) mutations account for a higher prevalence of polymicrogyria (21;77.8%) and simplified gyral pattern (7;100%). However, phenotype genotype correlations with specific mutations are found.

Deletions of the short arm of chromosome 5 is associated with Cri-du-chat syndrome (CdCs), a condition characterized by a high-pitched cat-like cry in newborns. Patients usually present with microcephaly, round face, hypertelorism, epicanthal folds, micrognathia, low-set ears, hypotonia, and severe developmental delay. CdCs is a contiguous gene syndrome, and even though it is a well defined clinical condition, the exact genotype-phenotype correlations remain to be established. However, the critical region for the cat-like cry has been located to 5p15.3, and the critical region for the intellectual disability has been suggested to be located within 5p15.2. We describe two patients with deletions of 73 kb and 3.2 Mb, respectively, that overlap part of the CdCs critical region in 5p15.2. Clinically our patients lack many characteristics of CdCs, but both have intellectual disability. Only *CTNND2*, encoding delta-catenin, is included in the deletion overlap between our two patients. *CTNND2* is predominantly expressed in brain and has been suggested to be involved in neuronal cell adhesion. The deletion of *CTNND2* in our two patients is likely causing their intellectual disability.

Goldberg-Shprintzen syndrome (GOSHS, MIM #609460) is an autosomal recessive disorder of intellectual disability, specific facial gestalt, and Hirschsprung disease. In 2005, homozygosity mapping in a large consanguineous family identified KIAA1279 as the disease-causing gene. KIAA1279 encodes KIF-binding protein (KBP), whose function is incompletely understood. Studies have identified either the mitochondria or the cytoskeleton as the site of KBP localization and interactions. To better delineate the KIAA1279-related clinical spectrum and the molecular mechanisms involved in GOSHS, we studied five new patients from three different families. The ho-

mozygous KIAA1279 mutations in these patients (p.Arg90X, Ser200X, or p.Arg202IlefsX2) led to nonsense-mediated mRNA decay and loss of KBP function. Despite the absence of KBP function, respiratory chain complex activity in patient fibroblasts was normal. KBP did not co-localize with mitochondria in human fibroblasts but interacted with the actin and tubulin cytoskeleton. KBP expression directly affected neurite growth in a neuron-like cell line (human neuroblastoma SH-SY5Y), in keeping with the central (polymicrogyria) and enteric (Hirschsprung disease) neuronal developmental defects seen in GOSHS patients. The KBP interactions with actin filaments and microtubules demonstrated in our study constitute the first evidence that an actin microtubule cross-link protein is involved in neuronal development in humans.

The Rett syndrome networked database (RSND) is a repository of clinical and molecular data for patients affected by Rett syndrome. Although it was initially targeting the european population of RTT patients, it is now open to countries outside of Europe. RSND is different from existing repository for Rett syndrome clinical and molecular data. First, RSND records are curated by experienced clinicians. This is important to exclude potential bias existing when clinical data is gathered using questionnaires sent out by mail to families. Second, RSND is currently the largest RTT database in the world with 1900 patients on file. This number could significantly increase in the next few months with the addition of cases from large countries such as Russia or India. Third, RSND is an open access initiative and data can be retrieved directly through a web-based search engine by all interested professionals. Records are de-identified but access to the invidiual patient files can be granted through the participating clinicians in each country.
We are providing here a description of the first 1900 records contained in the networked database and are discussing the content of RSND in the light of published guidelines for RTT, the development of clinical trials and with respect to other RTT cohorts.

A mutation in the DOPA decarboxylase gene (DDC) causes a new syndromic form of Intellectual Disability

***E. Bonora**[1], A. T. Wischmeijer[1,2], T. Pippucci[1], C. Diquigiovanni[1], M. Giambartolomei[1], A. Kurg[3], L. Garavelli[2], C. Fusco[4], C. Graziano[1], M. Seri[1], G. Romeo[1];*

[1]Unit of Medical Genetics, University of Bologna, BOLOGNA, Italy, [2]Clinical Genetics Unit, Istituto di Ricovero e Cura a carattere Scientifico, Arcispedale S. Maria Nuova,, Reggio-Emilia, Italy, [3]Institute of Molecular and Cell Biology, Tartu University, Tartu, Estonia, [4]Dept of Child Neuropsychiatry, Istituto di Ricovero e Cura a carattere Scientifico, Arcispedale S. Maria Nuova,, Reggio-Emilia, Italy.

Intellectual disability (ID) is characterized by a substantial below-average score on tests of mental ability, and limitations in functions related to areas of daily life. Two male sibs and a male first cousin, born of two double consanguineous marriages (first cousins once removed and second cousins), presented developmental delay and moderate mental retardation, craniofacial dysmorphisms and chronic diarrhea with or without recurrent hypoglycemia, gastro-esophageal reflux and progressive kyphoscoliosis.
SNP-array analysis (Affymetrix 6.0 platform) revealed no causative CNV. ROH analysis identified a shared region of homozygosity corresponding to the genomic coordinates chr7: 45,716,212-50,602,470.
Whole exome analysis identified a homozygous variant g.50,531,015 G>A in both affected sibs in the gene DDC (DOPA decarboxylase; aromatic L-amino acid decarboxylase). This variant causes a non-synonymous substitution p.Arg453Cys, predicted damaging by PolyPhen-2. Moreover, it co-segregates in the affected first cousin and is absent in 500 control Italian chromosomes. It therefore seems causative of the clinical phenotype in the patients.
Mutations in DDC have been reported in autosomal recessive DOPA-decarboxylase syndrome (OMIM 608643), but the clinical characteristics of our patients appear different from those previously described. Current analyses are ongoing to verify dopamine and serotonin levels in blood and liquor of the affected sibs, as well as functional studies on wild-type and mutant isoforms, for a better definition of the clinical features and etiology of this DCC variant. This work was supported by the EU-funded grant CHERISH (FP7 Health -2007).

P05.050

A further patient with a deletion 14q32.2, clinical features of maternal uniparental disomy 14 and pronounced intellectual disability: evidence for a novel microdeletion syndrome

***B. Albrecht**[1], K. de Groot[2], K. Buiting[1], H. Lüdecke[1];*

[1]Institut fuer Humangenetik, Essen, Germany, [2]MRC, Amsterdam, Netherlands.

We report on a female patient with a upd(14)mat-like phenotype. The patient is the second child of non- consanguineous Tunisian-Lebanese parents. Pregnancy started as a twin pregnancy. Recurrent bleedings and reduced fetal movements were observed. The patient was born by cesarean section with normal birth measurements at 36 weeks of gestation. Muscular hypotonia and poor sucking led to tube and PEG feeding during the first year of life. She is severely delayed, walking with 2 ½ years and talking with 4 years. Precocious puberty occurred with 5 years. With 3 years all her body measurements lay below the 3rd centile, with 13 years she was short, but weight and head circumference were normal. She shows facial dysmorphism with long, narrow face and hypertelorism, behavioral problems started with 12 years.
Karyotyping was normal. SNP-array hybridization and quantitative real-time PCR for the *MEG3* gene revealed a 1.1 Mb *de novo* deletion, including most of the imprinted genes of the region and 14 not imprinted genes (ar r[hg19]14q32.2q32.31(100.405.409-101.504.293)x1). Using MS-MLPA we detected hypomethylation of the *MEG3* promotor region, indicating that the deletion is of paternal origin.
Our patient carries the recurrent microdeletion 14q32.2 with breakpoints inside TGG repeats, as described for two patients by Bena et al in 2010, and two further patients, reported in 2012 by Ballif et al. She shows all clinical features of the previously described upd(14)mat-like phenotype, except for normal body measurements at birth. Haploinsufficiency of additional, non-imprinted genes may cause the intellectual disability of this novel microdeletion 14q32.2 syndrome.

Clinical and genetic: A study of 30 new cases with duplication of 15q11-q13 region

***E. I. Al Ageeli**[1,2], S. Drunat[3], C. Delanoe[4], L. Perrin[1], C. Baumann[1], Y. Capri[1], J. Fabre-Teste[1], A. Aboura[5], C. Dupont[5], L. El Khattabi[5], D. Chantereau[3], J. Gallard[6], A. Tabet[5], A. Verloes[1];*

[1]Medical Genetic Department, Denis Diderot Paris VII Universitiy and AP-HP, Robert Debré Hospital, Paris, France, [2]Jazan University, Jazan, Saudi Arabia, [3]Molecular Genetic Department, AP-HP, Robert Debré Hospital, Paris, France, [4]Physiology Department, AP-HP, Robert Debré Hospital, Paris, France, [5]Cytogenetic Department, AP-HP, Robert Debré Hospital, Paris, France, [6]Medical Genetic Department, AP-HP, Robert Debré Hospital, Paris, France.

Duplication of 15q11-q13 region results either from a supernumerary marker (SMC) derived of chromosome 15 or from an interstitial duplication (ID).

Duplications are characterized by hypotonia, developmental delay, speech delay, seizure, minor dysmorphic features and autism. A retrospective study of 30 unrelated patients with microduplication of the 15q11-q13 region showed 15 cases have a SMC15. In 14 the SMC was of large size, encompassing PWS/ASCR and one was paternal in origin. Furthermore, 15 cases with ID: 9 with typical duplication BP2-BP3, 1 with large duplication BP2-BP5 region and 4 with atypical duplication; one case had overlaps between BP1-BP2 and BP2-BP3 regions and 3 with duplication limited to three paternally expressed genes located in BP2-BP3 region. One case with duplication BP1-BP2. Four cases were inherited from normal parents (3 maternal and 1 paternal). Phenotypic features were highly variable and 74% presented with autism. Twelve patients showed cerebral anomalies and 14 patients had an unusual EEG pattern of diffuse fast rhythms even in absence of epilepsy that appears to be characteristic for duplication 15q11-q13 syndrome which could help in early diagnosis of this syndrome.

Clinical performance and diagnostic yield assessment of the Affymetrix CytoScan® Dx cytogenetic microarray system

A. Chaubey[1], *K. Kwiatkowski*[2], *A. Roter*[2], *S. Close*[3], *R. Pfundt*[4], *E. Thorland*[5], *B. R. DuPont*[1], *J. Reiswig*[2], *R. Hockett*[6], *E. T. Fung*[2];
[1]*Greenwood Genetic Center, Greenwood, SC, United States,* [2]*Affymetrix, Santa Clara, CA, United States,* [3]*GenEngine, Fishers, IN, United States,* [4]*Radboud University Medical Centre, Nijmegen, Netherlands,* [5]*Mayo Clinic, Rochester, MN, United States,* [6]*CombiMatrix Diagnostics, Irvine, CA, United States.*

Cytogenetic microarrays have demonstrated a significant increase in the diagnostic yield assessment by identifying pathogenic copy number changes as compared to traditional techniques such as karyotyping and fluorescence in-situ hybridization. The diagnostic yield of CytoScan® Dx was assessed in a cohort of individuals exhibiting intellectual disability, congenital anomalies, and/or dysmorphic features. Consecutive IRB-approved, DNA samples were de-identified and collected at three clinical laboratory sites. Routine patient care (RPC) comprised of one or more of traditional cytogenetic methods, Fragile X testing and microarray (excluding Affymetrix array) for determining genomic alterations/rearrangements. Samples were run at one site on CytoScan® Dx and the data were interpreted by an independent cytogeneticist blinded to any patient information.
In total, 960 samples were analyzed. The diagnostic yield from RPC (excluding all microarray platforms) was 14.5% (95%CI = 9.6-21.3%). On the same sample set, the diagnostic yield from CytoScan® Dx was 23.9% (95%CI = 17.6-31.7%), indicating a net 9.4% incremental yield provided by CytoScan® Dx. Notably, 20 pathogenic alterations were identified by CytoScan® Dx that were not detected by RPC methodologies.
This is the largest study to date assessing the diagnostic yield of CytoScan® Dx as compared to RPC and confirms previous results that whole genome microarrays provide a clinically significant increase in diagnostic yield.

P05.053

Small deletion detected by MPLA in the 22q11 region in a patient with attention deficit and behavioral disorders

F. Gonzalez, *A. Zuñiga, L. Pedrola;*
Hospital de la Ribera, Alzira (Valencia), Spain.

DiGeorge syndrome (DGS, #188400) is actually a well-defined primary immunodeficiency disorder classically associated with congenital heart defects, and hypoparathyroidism with hypocalcaemia. The facial appearance of patients with DGS is characterized by hypertelorism, micrognathia, short philtrum with "fish-mouth", antimongoloid slant, and telecanthus with short palpebral fissures. It has been reported that children and adults with DGS have high rates of behavioral, psychiatric and communication disorders. CASE REPORT: Our case report was a 13.8-year-old boy born to unrelated healthy parents. Initially, he was admitted to the Neuropaediatric Department with attention deficit and socialization problems. At physical examination, mild facial dysmorphism was noted. The laboratory investigations revealed normal parathormone levels, but the presence of hypocalcemia and hyperphosphatemia suggested a possible hypoparathyroidism. Patient had no cardiac defects, no immunodeficiency and normal thyroid hormone levels. MLPA analysis was performed using P-245 B1 kit. A deletion in 22q11 region was detected located in the AB region (*CLDN5* and *GP1BB* gene). Deletions in 22q11 are the most frequent cause of DGS, the majority include the AB, BC and CD regions, though some deletions are smaller (AB only as our case) or larger. Patients with chromosome 22q11.2 deletion do not always show all components of DGS. Hypoparathyroidism can be the only abnormality and may exist with no accompanying cardiac or immunologic defects. DGS patients do not always have the typical dysmorphic features and may not be diagnosed until adulthood. DGS is relatively common and this diagnosis should be considered in patients with mental, behavioral, or attention disorder.

P05.054

Global transcriptome profiling reveals involvement of genes localized across different chromosomes in pathogenesis of Down Syndrome

A. Pathak, *S. R. Phadke;*
Department of Medical Genetics, Sanjay Gandhi Post Graduate Institute Of Medical Sciences, Lucknow, India.

Down syndrome (DS), the most frequent genetic disorder leading to mental retardation is caused by partial or complete triplication of human chromosome 21. The differential expression of genes located on extra chromosome 21 is generally assumed responsible for phenotypic abnormalities but this gene dosage hypothesis has not been fully assessed on genome-wide basis. The expression patterns of genes related to phenotypic abnormalities may provide insights into their roles in pathogenesis of DS. To analyze the differential gene expression and understand the molecular mechanism underlying pathogenesis of DS, we performed global gene expression profiling in blood samples of 9 DS and 1 normal subjects using human whole transcriptome microarray. The microarray analysis revealed total of 22 genes present on chromosome-21 showing differential expression. Genes involved in physiological pathways such as apoptosis regulation, cell cycle regulation, signal transduction, cell maturation, and immunity showed dysregulation. Several genes localized on chromosome-21 such as APP, SOD1, DYRK1A, COL6A1 showed similar expression levels across all DS subjects. Interestingly, several non chromosome-21 genes such as RCAN3 (chromosome 1), ANK3 (chromosome 10), CDK17 (chromosome 12) etc., having roles in cardiogenesis, signal transduction and differentiation of neurons showed conserved levels of expression across the DS subjects. The gene dosage hypothesis on chromosome-21 may partially explain the neurological and other symptoms but our results substantiate the involvement of genes localized across different chromosomes in pathogenesis of DS. Our data may provide the basis for a more systematic and improved understanding of molecular mechanism underlying the pathogenesis of the disease.

A complex chromosomal rearrangement with X-autosome translocation and PCDH19 gene duplication in a girl with drug resistant epileptic encephalopathy

M. Piechota[1], *M. Wysocki*[1], *M. Badura-Stronka*[1,2], *A. Wilczewska-Wiktor*[3], *B. Steinborn*[3], *A. Latos-Bieleńska*[1,2];
[1]*Center for Medical Genetics GENESIS, Poznan, Poland,* [2]*Chair and Department of Medical Genetics, Poznan University of Medical Sciences, Poznan, Poland,* [3]*Chair and Department of Child Neurology, Poznan University of Medical Sciences, Poznan, Poland.*

The advent of CGH microarray technique helps to define abnormalities in chromosome structure very precisely and therefore seems to be a perfect tool for medical genetics.
We describe a case of a 6 year old girl with profound mental retardation and drug resistant epileptic encephalopathy. Derivative chromosome X, observed in karyotype was further characterized by CGH microarray technique. Three pathogenic aberrations were identified: 34Mb duplication in chromosome 2 (2p25.3-2p22.3), 57Mb interstitial duplication in chromosome X (Xq21.33-Xq28) and 2.7Mb duplication in chromosome X (Xq28), with a translocation of a fragment of the short arm of chromosome 2 onto the long arm of chromosome X. More than 600 genes have been characterized in the above mentioned regions. The 57Mb duplication encompassed protocadherin 19 (PCDH19) gene, involved in female-restricted epilepsy-mental retardation syndrome (EFMR). So far, PCDH19 mutations have been identified in affected heterozygous females and in asymptomatic hemizygous males. A random X inactivation is expected to disturb cell-to-cell interactions leading to the phenotype of mutated females. The influence of the X-autosome translocation in the patient on the X-inactivation pattern and the phenotype

is discussed in detail.

Case report of a de novo 17q12q21.32 duplication of 9.2 Mb in a girl with hypotonia, facial dysmorphism, and cardiac abnormalities

T. Ait Mouhoub[1,2], *M. Doco-Fenzy*[1,3,2], *E. Landais*[1,4,2], *C. Leroy*[1,2], *A. Lannoy*[1,2], *P. Mauran*[1,5], *P. Sabouraud*[1,5], *P. Morville*[1,5], *P. Feucher*[1,2], *S. Clomes*[1,2], *N. Gruson*[1,2], *C. Mangeonjean*[1,2], *D. Gaillard*[1,3,2];

[1]CHU Reims, Reims, France, [2]Service de génétique, Reims, France, [3]SFR CAP-SANTE,URCA Reims, EA3801, Reims, France, [4]PRBI, Reims, France, [5]Service de pédiatrie, Reims, France.

Background: Duplication in 17q21 region are rare. Microduplication of the region 17q21.31 (OMIM 613533) reciprocal to the classical 17q21.31 deletion of 500.000 bp has been reported in 6 cases with variable facial dysmorphism, psychomotor delay, hypotonia, abnormal digits, hirsutism (decipher and literature). We report a patient with a large duplication of 9.2Mb (17q12-q21.32) encompassing this microduplication.

Method: The duplication was diagnosed by classical cytogenetics showing a longer 17q arm and mapped with array-CGH (Agilent 180k). 46,XX,dup(17)(q12q21.32).arr 17q12q21.32(36,473,175-45,620,194)x3 dn. Parental karyotypes were normal.

Clinical report: We report a female patient born at 35 weeks of gestational age with weight 2.6 kg(M), OFC 32 cm(M). She was referred for severe hypotonia, feeding difficulties, facial dysmorphism with large frontal bossing, hypertelorism, asymmetrical eyeballs, strabism, synophris, anteverted nostrils, everted lower lip, micrognathia, plagiocephaly, hirsutism. On cardiac ultrasound persistent foramen ovale, apical ventricular septum defect, persistent left superior venous cava were found. At 16 months of age she could sit but not walk, she had feeding difficulties and growth delay with weight 7020 g (-3SD), length 78.5 cm (M) and OFC 45cm (-1SD).

Conclusion: To our knowledge, this case is the first reported with a de novo 17q12-q21.32 duplication. Compared to the reported 17q21.31 duplication syndrome, in the present case, the common symptoms are : hypotonia, psychomotor retardation, synophris, hirsutism, micrognathia, high-vaulted palate. The discrepant features are : ophthalmic asymmetry, hyperlaxity, facial dysmorphism, and cardiac abnormalities.

Reading is one of the pillars of education and a central skill to succeed in our information-based society. Dyslexia is a reading disorder with a prevalence of approximately 10% of the population. The aim of this study is to identify genetic variants associated with Dyslexia and to integrate genetic and cognitive-behavioural markers to establish causal links and promote early diagnosis. To that end, we performed a genetic association study to identify patterns of DNA-polymorphisms that vary between individuals with different cognitive phenotypes following two strategies. On the one hand, we are carrying out a Genome-Wide-Association-Study (GWAS), analyzing 730000 Single Nucleotide Polymorphisms (SNPs) along the genome in a subset of dyslexics and controls. Preliminary analyses have identified 11 SNPs associated with Dyslexia with a P-value of 10-6, which should be conveniently validated. On the other hand, we are following a candidate gene association approach focusing on individual polymorphisms that have been reported to be implicated in cognitive disorders. We have genotyped variants of KIAA0319, DCDC2, FOXP2, DYX1C1, COMT1, DBH, MAOA, DRD4 and DAT1 genes in 4700 individuals. The missense SNP rs4504469 located within the KIAA0319 gene shows the highest association with Dyslexia in the studied population (p<10-2). In addition, we will present the relationships between the genotype of these candidate genes and cognitive-behavioural variables such as Intelligence quotient and reading ability among the general Spanish child population.

Early onset epileptic encephalopathies (EOEE) are rare and severe disorders in which patients have impaired cognitive development. A part of EOEEs, known as Ohtahara syndrome (OS), is characterised by the association of frequent motor seizures occurring before three months of age, with an EEG showing a "suppression-burst" pattern. The prognosis is classically poor with drug resistant epilepsy and a majority of patients evolving into West Syndrome.

Cases related to brain structural or metabolic abnormalities have been discarded, to consider genetic causes. Several genes have been described in the pathology ARX, SLC25A22, STXBP1 and KCNQ2.

Here, we have collected a cohort of 105 patients with EOEE. In order to identify key clinical features and perform genotype-phenotype correlations, EOEE patients are screened for the known genes. We found 8 patients mutated for STXBP1 and 15 patients mutated for KCNQ2. Interestingly, the two groups evolve in the same feature with a remission of the epilepsy in the majority of patients. We have already shown that the course of the epilepsy was unexpected in patients having a mutation of STXBP1. KCNQ2 patients all had a neonatal onset of the epilepsy and have heterogeneous evolution, with mild phenotype in some cases or dramatic outcome in other cases. In both groups, very few patients evolved into West syndrome, although this has classically been described for OS patients.

In conclusion, this study confirms that KCNQ2 and STXBP1 are mutated in EOEE and associated with variable outcome.

Early infantile epileptic encephalopathy caused by mutations in PCDH19 and CDKL5 genes

S. Tincheva[1], *A. Kirov*[1,2], *P. Dimova*[3], *A. Todorova*[1,2], *B. Sukhudyan*[4], *T. Todorov*[1], *V. Mitev*[2];

[1]Genetic Medico-Diagnostic Laboratory Genica, Sofia, Bulgaria, [2]Medical University Sofia, Sofia, Bulgaria, [3]St. Naum University Hospital of Neurology and Psychiatry, Sofia, Bulgaria, [4]"Arabkir" Joint Medical Center and Institute of Child and Adolescent Health, Yerevan, Armenia.

Early infantile epileptic encephalopathy (EIEE) is a severe form of epilepsy characterized by frequent tonic spasms with onset in the first months of life. The disease course is severe with early death or marked psychomotor retardation.

Here we report three female EIEE patients. All of them suffered by tonic seizures in clusters, appearing soon after birth, at 5th and 6th month of age respectively.

In both patients with onset between 5th and 6th month and the seizure type, suggested screening for mutations along the PCDH19 gene as a first step. In contrast, the very early onset of the tonic seizures in the last patient supposed CDKL5 related epileptic encephalopathy. The molecular-genetic

testing of the PCDH19 gene showed the following mutations: c.2705dupA p.(Asp902Lysfs*6) and c.1091delC; p.(Pro364Argfs*4). Although the mutations are situated in different protein regions (extracellular domain 4 and cytoplasmic domain) the clinical features are almost the same. The possible explanation is the nonsense-mediated mRNA decay.
The last patient was found to be a heterozygous carrier of a de novo CDKL5 missense mutation c.539C>T; p.(Pro180Leu). This mutation affects the catalytic domain of the protein and thus causes a typical clinical phenotype with very early onset.
The EIEE syndromes are one of the main groups of severe neonatal epilepsies with suppression-burst pattern. Although, the phenotypes vary, some clinical features and the seizure onset could be used to guide the molecular genetic testing algorithm.

Early-onset epileptic encephalopathies (EOEEs) are a group of rare devastating epileptic syndromes of infancy characterized by severe drug resistant seizures and electroencephalographic abnormalities. The current study aims to determine the genetic etiology of a familial form of EOEE fulfilling the diagnosis criteria for malignant migrating partial seizures in infancy (MMPSI). We identified two inherited novel mutations in TBC1D24 in two affected siblings. Mutations severely impaired TBC1D24 expression and function, which is critical for maturation of neuronal circuits. The screening of TBC1D24 in an additional set of 8 MMPSI patients was negative. TBC1D24 loss of function has been associated to idiopathic infantile myoclonic epilepsy, as well as to drug resistant early onset epilepsy with intellectual disability. Here we describe a familial form of MMPSI due to mutation in TBC1D24, revealing a devastating epileptic phenotype associated with TBC1D24 dysfunction.

P05.061
Disruption of estrogen receptor beta gene in a three generation family with mild intellectual disability

***R. Rupps**[1], C. du Souich[1], A. Chou[1], P. Atkins[1], P. Stankiewicz[2], C. van Karnebeek[1], C. F. Boerkoel[1];*
[1]University of British Columbia, Vancouver, BC, Canada, [2]Baylor College of Medicine, Houston, TX, United States.

We report an apparently balanced reciprocal translocation with breakpoints at 14q22 and 18q21 segregating with mild intellectual disability, speech delay and dysmorphic features in a three generation family. This translocation interrupts the estrogen receptor beta gene (*ESR2)*.
Routine cytogenetic analysis (>500 band resolution) showed an apparently balanced translocation: 46,XY,t(14;18)(q22;q21) in the affected family members. No significant copy number variations were detected on chromosomal microarray.
The translocation breakpoints were defined using LR PCR. The breakpoint region on chromosome 18 does not contain any annotated genes and the region on chromosome 14 contains only *ESR2*. Disruption of this gene was confirmed by FISH.
Estrogen receptor beta is part of the nuclear receptor superfamily, but pools of this receptor are also localized to the plasma membrane and mitochondria. Estrogen receptor beta is expressed in mammary glands, ovaries, bones and brain and has been implicated in cardiovascular and brain functioning as well as in inflammation, bone physiology and various types of cancer.
Evidence for the pathogenicity of *ESR2* come from animal studies where *Esr2* knockout mice display morphologic brain abnormalities and disruption of the gene impairs memory, learning and mood. This three-generation family illustrates the first human disease arising from mutation of *ESR2*. Better understanding of the molecular and physiologic basis of the disease in this family will increase understanding of the genetic causes of intellectual impairment and the complex role of estrogen in human physiology.

P05.062
Whole-exome sequencing study in patients with intellectual disability.

***M. Sauk**[1], M. Nõukas[1], T. Pippucci[2], F. Balombo[2], L. Milani[3], G. Romeo[2], A. Kurg[1];*
[1]University of Tartu, Tartu, Estonia, [2]University of Bologna, Bologna, Italy, [3]Estonian Genome Center, Tartu, Estonia.

Whole-exome sequencing is a powerful tool in discovery of disease causing mutations. Nevertheless the etiology of intellectual disability (ID) remains unknown in about 50% of the cases. Affecting 1–3% of the general population, the cause of ID is very heterogeneous and can be involve environmental and genetic factors.
We carried out within the framework of EU FP-7 CHERISH project (#223692) whole-exome sequencing analysis in 21 patients with idiopathic ID from 12 families, where two of the families were known to be consanguineous. The patients were expected to have X-linked, recessive or dominant inheritance pattern. For exome enrichment we used Illumina's TruSeq 62Mb Enrichment Kit and next-generation sequencing experiment was performed using Illumina's HiSeq 2000. The average read depth for sequenced exomes was 70-fold.
For the analysis we used BWA to map the data to reference human genome version 19; GATK for local realignment, removing PCR duplicates and base quality recalibration; and ANNOVAR for annotating variants.
We found variants in autosomal and X-linked genes, on average about 93 000 variants per patient. After filtration, we found possibly clinically relevant changes in upto six genes per family, that are important in development of nervous system. All the candidate variants were confirmed by Sanger sequencing and segregation within the family were checked. The further analysis of these variants is currently in progress.
For additional analysis we plan to implement two split read–based approaches Splitread and Pindel for discovery of medium size indels in these exome data sets, that are too long for BWA.

P05.063
Role of CTCF protein in regulating FMR1 locus transcription

***S. Lanni**[1], M. Goracci[1], L. Borrelli[1], P. Chiurazzi[1], U. Moscato[2], F. Ferrè[3], M. Helmer-Citterich[3], E. Tabolacci[1], G. Neri[1];*
[1]Istituto di Genetica Medica, Università Cattolica del Sacro Cuore, Rome, Italy, [2]Istituto di Igiene, Università Cattolica del Sacro Cuore, Rome, Italy, [3]Dipartimento di Biologia, Università di Roma "Tor Vergata", Rome, Italy.

Fragile X syndrome (FXS), the leading cause of inherited intellectual disability, is caused by expansion and methylation of a CGG triplet repeat at FMR1 gene. While DNA methylation of the promoter is the major cause responsible for FMR1 silencing, other factors may be implicated. Several nuclear proteins bind to the promoter of FMR1, like the insulator protein CTCF. Here we show that CTCF does not bind to FXS alleles, whereas it binds equally to wild type (WT) and to unmethylated full mutation (UFM) alleles. In FXS cells CTCF binding cannot be restored by drug-induced demethylation of the DNA. In UFM and WT cells CTCF binds to the methylation boundary upstream the promoter, even though it does not act as insulator of the FMR1 locus. CTCF knock-down results in FMR1 transcription reduction and heterochromatic histone configuration of the locus, which however is not accompanied by spreading of DNA methylation towards the FMR1 promoter. A CTCF binding site is present in intron 2 of FMR1, where one of the transcriptional start sites of antisense transcript is located. CTCF depletion is also associated with antisense FMR1 transcript reduction. The antisense transcript is upregulated in UFM cells, its expression and splicing is closely paralleled by that of the sense transcript. We conclude that CTCF has a complex role in regulating FMR1 expression, probably through the organization of chromatin loops between sense/antisense transcriptional regulatory regions, as suggested by a bioinformatics analysis.

P05.064

Congenital RTT variant in a Bulgarian patient, caused by mutation in FOXG1 gene

A. V. Kirov[1,2], *I. Litvinenko*[3], *T. Todorov*[2], *A. Todorova*[1,2], *R. Tincheva*[3], *V. Mitev*[1];
[1]Medical University Sofia, Sofia, Bulgaria, [2]Genetic Medico-Diagnostic Laboratory Genica, Sofia, Bulgaria, [3]University Pediatric Hospital, Medical University Sofia, Sofia, Bulgaria.

Rett syndrome (RTT, MIM #312750) is mostly caused by mutations in the X-linked MECP2 gene and mutations have been identified in 95-97% of typical RTT patients, but only in 50-70% of atypical cases. This indicates both genetic and clinical heterogeneity of the RTT variants. Over the last years, mutations in the FOXG1 genes have been associated with congenital RTT variants. Here we report a 4 years old girl who has been clinically diagnosed as RTT. She had normal occipitofrontal head circumference (OFC) at birth and deceleration of head growth from birth, current OFC centile 45 cm, microcephaly (standard deviation score, SDS - 3,43). The patient suffered from sleep disturbances, mood lability and inconsolable crying. The regression started at 5 months of age. The seizure onset was after regression - 11 months of age. Additional features were: severe intellectual disability, severely impaired language, hypotonia, stereotypic hand movements, no ability to walk, bruxism and convergent strabismus. The molecular genetic analysis for mutations in MECP2 gene was negative. The specific phenotype classified the patient as congenital RTT variant and screening for FOXG1 mutations was performed. A novel heterozygous nonsense mutation c.406G>T, p.Glu136* was detected. The detected mutation is situated in the N-terminal protein domain, in the region mostly affected by frameshift disruptions. Our results show how important the strict clinical criteria for distinguishing RTT variants are, in order to be able to offer the family adequate molecular genetic testing.

P05.065

Behavioral phenotype of 8 patients with fragile X syndrome

m. trabelsi[1], *r. sakka*[1], *n. gharbi*[1], *f. maazoul*[1], *l. kraoua*[1], *i. ouertani*[1], *r. meddeb*[1], *a. belhadj*[2], *r. mrad*[1], *h. chaabouni*[1], *T. Tunisian Network on Mental Retardation*[3];
[1]service des maladies congenitales et hereditaires, tunis, Tunisia, [2]service de psychiatrie, hôpital Razi, tunis, Tunisia, [3]Tunisian Network on Mental Retardation, tunis, Tunisia.

Fragile X syndrome (FXS) is the most common inherited cause of intellectual disability due to an expansion in the full mutation range (>200 CGG repeats) of the promoter region of the FMR1 gene leading to gene silencing. Lack of the corresponding protein FMRP will cause FXS which is characterized by intellectual deficiency, behavioral disorders, facial dysmorphy and macroorchidism. Here we report on the behavioral profile of eight patients showing a confirmed FXS. The parents' interview revealed that all patients expressed symptoms of autism spectrum disorder (ASD). Aggression and self-injury were found in 6 patients, stereotyped patterns of behaviors, interests, and activities were noted in 4 patients and attention issues were observed in 4 patients. Only one patient fulfilled the criteria for infantile autism. Other behavioral anomalies were also seen such hyperactivity (5 patients/8) and psychotic disharmony (1patient/8). These results confirm the heterogeneity of behavioral profile in FXS and the common association between FXS and autistic disorders. Such study, considering the behavioral phenotype of genetic syndromes, like FXS, allows us to explain associated psychiatric disorders, to adjust the assessment of intellectual disability level, to adapt educational guidance and rehabilitative plans and to update patient screening in the future.

P05.066

Reactivation of the FMR1 gene in fragile X lymphoblastoid cells by 5-aza-2-deoxycytydine does not cause random genomic DNA demethylation

G. Mancàno, *S. Lanni, M. Goracci, M. Moscarda, E. Tabolacci, P. Chiurazzi, G. Neri;*
Università Cattolica del Sacro Cuore, Rome, Italy.

Fragile X syndrome (FXS) is caused by CGG expansion over 200 repeats at the 5' UTR of the FMR1 gene and subsequent DNA methylation of both the expanded sequence and the CpGs of the promoter region. This epigenetic change causes transcriptional silencing of the gene. We have previously demonstrated that 5-aza-2-deoxycytydine (5-azadC) treatment of FXS lymphoblastoid cells reactivates the silent gene, allowing CpG sites demethylation, increased acetylation of histones H3 and H4 and methylation of lysine 4 on histone 3. Recently we observed that reactivation of FMR1 transcription is long lasting, up to a month after a 7-days treatment with 1 μM 5-azadC, and that maximum level of transcription are reached 10-15 days after 5-azadC last administration. In order to check the specificity of the 5-azadC-induced DNA demethylation, we performed bisulphite sequencing of the entire methylation boundary upstream the FMR1 promoter region, which is preserved in WT cells [Naumann et al., 2009]. We did not observe any modification of the methylation boundary after the treatment. Furthermore, methylation analysis by MS-MLPA of PWS/AS and BWS/SRS loci demonstrated that 5-azadC treatment has no demethylating effect on these regions. Taken together these data show that 5-azadC has a long lasting reactivating effect on the mutant FMR1 gene and that its demethylating effect on genomic DNA is not random but rather restricted to specific regions. This specificity of action may open new perspectives for a drug-based epigenetic therapy of FXS.

P05.067

BKCa channels: a new therapeutic target in Fragile X Syndrome treatment

B. Hebert[1], *O. Perche*[2], *A. Menuet*[1], *N. Doisne*[1], *J. Pichon*[1], *B. Laudier*[1], *S. Briault*[2];
[1]CNRS - UMR7355 - UNIVERSITY OF ORLEANS, Orleans, France, [2]CHRO - CNRS - UMR7355 - UNIVERSITY OF ORLEANS, Orleans, France.

The most common cause of inherited mental deficiency (MD) associated with autistic features, Fragile X Syndrome (FXS), results from the *FMR1* gene silencing and loss of Fragile X Mental Retardation Protein (FMRP). Among synaptic proteins deregulated by the absence of Fmrp in *fmr1* knock-out (KO) mice (murine model for FXS), Kcnma1 (α-subunit of large conductance Ca^{2+}-activated potassium channels, BKCa) seems to be the most significant deregulated one. Since several papers showed an involvement of BKCa channels in MD, this channel could be a new therapeutic target for FXS.

The objectives of this study were: 1) to characterize the molecular BKCa channel anomaly in *fmr1* KO mouse model and 2) to evaluate the therapeutic effect of a BKCa channel opener molecule (BCOM), BMS-204352, on dendritic spines maturation of *fmr1* KO neurons and on social behavior of *fmr1* KO mice. In *fmr1* KO mice, Kcnma1 protein quantity was lower in cerebral structures and neurons, and associated with a reduced BKCa whole cell current. *In vitro* addition of BMS-204352 induced dendrite spines maturation of *fmr1* KO neurons. *In vivo*, using a behavioral test of direct social interaction, a single injection of BMS-204352 rescued affiliative behaviors to wild-type level.

In conclusion, we demonstrated 1) a Kcnma1 protein anomaly in *fmr1* KO mice inducing a decrease in BKCa whole cell current, and 2) that a BCOM, BMS-204352, restored a regular phenotype of dendrite spines and social interaction in *fmr1* KO mice. Therefore, BKCa channel could be a new therapeutic target in FXS treatment.

Detection of full mutation FMR1 and AFF2 alleles by Methylation-Specific Multiplex Ligation-dependent Probe Amplification method in male patients with intellectual disability

I. Sansović, *I. Barišić;*
Children's Hospital Zagreb, Zagreb, Croatia.

Mutations in genes FMR1 and AFF2 on X chromosome cause Fragile X (FXS) and Fragile XE (FRAXE) syndromes respectively, two common forms of inherited intellectual disability in men. The most frequent alteration in these genes is the abnormal extension of trinucleotide repeats in exon 1 and abnormal gene methylation. Based on the number of trinucleotide repeats, there are four types of the alleles: normal, intermediate, premutation and full mutation. Patients with full mutation alleles usually display classic form of FXS.

Methylation-Specific Multiplex Ligation-dependent Probe Amplification (MS-MLPA) method enables detection of deletions/duplications, and also analysis of methylation status of promoter of FMR1/AFF2 gene.

We have analyzed 17 male patients with FXS and one male patient with FRAXE by MS-MLPA method previously tested by Expand-long PCR method; 12

with FMR1-full mutation, three mosaics with FMR1-full mutation and normal /premutation alleles, two with FMR1-normal allele and FXS phenotype and one with AFF2-full mutation. MS-MLPA analysis has shown hypermethylation pattern of full mutation in all but one subject which has normal FMR1 allele. In subject in whom karyotype analysis showed 36% of cells with fragile X chromosome and Expand-long PCR one normal allele, MS MLPA revealed FMR1- full mutation allele.
MS-MLPA method enables clear and reliable distinction between normal/premutation and full mutation FMR1/AFF2 alleles in male subjects that makes it suitable for a screening method. Also, it is highly sensitive and therefore useful in clarification of FXS mosaic cases which Expand-long PCR method was unable to detect.

The goal of the CHERISH project was to establish an interdisciplinary Eastern Europe and Central Asia consortium of experts to perform a research program of clinical, scientific and public activities for generation of new knowledge about genetic causes of Intellectual Disability (ID). One of the main objectives was to identify genomic rearrangements responsible for ID using SNP-arrays. To screen the CNVs in 24 patients, we used the Genome-Wide Human SNP Array 6.0 (Affymetrix, 1M). In 36 patients, the InfiniumHD whole-genome genotyping assay with the HumanCytoSNP-12 BeadChips (Illumina Inc., 300k) was performed. Twelve potentially pathogenic (9 de novo) rearrangements were found in 10 out of 60 investigated individuals (16,7%), with all rearrangements confirmed by qPCR or MLPA. In Table 1 the most interesting findings have been listed.
Table 1. Selected genomic rearrangements in Polish patients identified by SNP-arrays within the CHERISH project.

Patient number	Rearrangement	Genomic position	Comment
309-POL-001-045	dup11q13.3q13.4	70,308,218-70,478,809	autism susceptibility locus (*SHANK2*)
652-POL-002-123	delXq21.1 in a female patient	76,907,922-77,078,030	deletion within *ATR-X* gene for alpha talasemia mental retardation syndrome
655-POL-001-124	del11q13.1	65,952,841-66,768,341	encompassing genes that are involved or may be involved in ID: *NPAS4, BBS1*

The research is funded by the European Community's 7th FP [FP7/2007-2013] under grant agreement n° 223692, CHERISH project.

Study of a large Spanish cohort of 22q13 deletion syndrome´s patients. A genotype-phenotype correlation?

***J. Nevado**[1,2], M. Palomares[1,2], F. Santos[1,2], E. Vallespin[1,2], A. Delicado[1,2], S. García-Miñaúr[1,2], M. L. de Torres[1,2], M. A. Mori[1,2], M. Milá[3,4], M. Del Campo[5], L. Armengol[6], E. Guillén[7], J. Rosell[8], E. Galán[9], L. D. Pablo[1,2];*
[1]INGEMM-IdiPaz, Madrid, Spain, [2]CIBERER, Madrid, Spain, [3]Hospital Clinic, Barcelona, Spain, [4]CIBERER, Barcelona, Spain, [5]Hospital Vall d´Hebron, Barcelona, Spain, [6]Q-Genomics, Barcelona, Spain, [7]Hospital Virgen de la Arrixaca, Murcia, Spain, [8]Hospital Son Espases, Palma de Mallorca, Spain, [9]Hospital Materno Infantil Infanta Cristina, Badajoz, Spain.

Phelan-McDermid Syndrome (PMS) is a neurodevelopmental disorder caused by the deletion or disruption of a 22q13 region containing the post-synaptic protein gene *SHANK3*. The clinical features of PMS (also known as 22q13 deletion syndrome) are highly variable and include hypotonia, speech and otherdevelopmental delays, autistic traits and mildly dysmorphic features. Other less frequent features include seizures, brain, renal and cardiac malformations, motor deficits, and lymphedema Patient deletion sizes are also highly variable, Clinical expression also varies widely, even among patients with small deletions, and no correlation between deletion size and phenotype has been found. A role for additional genetic factors, in addition to *SHANK3* haploinsufficiency, is likely. Because PMS is considered to be underdiagnosed, the true prevalence is unknown.
Aims. We aim to define a possible genotype phenotype comparison to use high-resolution deletion breakpoint mapping on a large cohort of patients, addressed the hypothesis that additional genes or regions of chromosome 22q13 besides SHANK3 may contribute to the PMS phenotype.
Results. Terminal deletion breakpoints were identified for more than 50 individuals in a patient cohort using a custom-designed high-resolution oligonucleotide array comparative genomic hybridisation platform, prompting this genotype phenotype association study. Most of them have been studied by FISH, MLPA and array-CGH and their clinical features have been defined. Interestingly, a great genetic variability, with deletion sizes between 10 Kb and as much as 9 MB was found.
Conclusions. Preliminary data from this large cohort (first, with Spanish patients) were presented and may it provide additional data on genotype-phenotype hypothesis.

A novel recessive intellectual disability syndrome caused by GPI-anchor deficiency

***M. Kvarnung**[1], D. Nilsson[1], A. Lindstrand[1], C. Korenke[2], S. Chiang[3], E. Blennow[1], M. Bergmann[4], T. Stödberg[5], O. Mäkitie[1], B. Anderlid[1], Y. Bryceson[6], M. Nordenskjöld[1], A. Nordgren[1];*
[1]Dept of Molecular Medicine and SurgeryKarolinska Institutet, Stockholm, Sweden, [2]Klinikum Oldenburg Zentrum für Kinder- und Jugendmedizin (Elisabeth Kinderkrankenhaus), Oldenburg, Germany, [3]entre for Infectious Medicine, Karolinska Institutet,, Stockholm, Sweden, [4]7Institute for Neuropathology, Klinikum Bremen-Mitte, Bremen, Germany, [5]Department of Women´s and Children´s Health, Karolinska Institutet, Stockholm, Sweden, [6]6Centre for Infectious Medicine, Department of Medicine, Karolinska Institutet,, Stockholm, Sweden.

Syndromes with a phenotype that include intellectual disability and/or seizures are clinically and etiologically heterogeneous, rendering diagnostic challenges. In the present study, we used whole exome sequencing (WES) to delineate the molecular basis for an autosomal recessive syndrome. We examined four patients in a consanguineous kindred with a strikingly similar phenotype, characterized by distinct facial features, intellectual disability, hypotonia and seizures, in combination with skeletal and ophthalmologic findings. WES identified a homozygous mutation in a gene previously not reported in any human disease, and Sanger sequencing of additional family members confirmed segregation with the disease. The gene encodes a protein in the GPI-anchor pathway, and by flow-cytometry we found that leukocytes from the patients had significantly reduced levels of the protein, strongly supporting the pathogenicity of the mutation. In addition, loss of function of the gene in a morpholino-mediated zebra-fish knock-down model led to a gastrulation defect. Our results demonstrate a new pathogenic mechanism in the GPI-anchor pathway and expand the spectrum of disorders belonging to the emerging group of GPI-anchor deficiencies.

P05.072

HDAC1: a novel cause of autism, developmental delay and epilepsy

***M. J. DASOUKI**[1], J. Roberts[1], W. Zeng[2], S. Mullegama[3], K. Gonzales[2], S. Elsea[3];*
[1]University of Kansas Medical Center, Kansas City, KS, United States, [2]Ambry Genetics, Aliso Viejo, CA, United States, [3]Virginia Commonwealth University, Richmond, VA, United States.

Autism and epilepsy are clinically and genetically heterogeneous disorders. Epilepsy occurs in 25% of patients with autism. Chromosomal Microarray Analysis (CMA) and massively parallel sequencing have identified a large number of genomic regions as well as specific genes which confer susceptibility to autism. Six pathogenic copy number variants (4 deletions and 2 duplications) which ranged from 1.3 -17.2 Mb and overlapping the HDAC1 gene had been reported. HDAC1, a histone deacetylase, directly interacts with MeCP2 through the transcription co-repressor Sin3A/HDAC complex. Mutations in MECP2 cause Rett syndrome; however, no mutations have been described in HDAC1 so far. In a 10 year old boy with non-syndromic autism, developmental delay and epilepsy, routine karyotype, CMA, metabolic, and neuroimaging studies were normal. Whole exome sequencing of

gDNA from the boy and his parents identified a de novo, novel variant in HDAC1 (c.154N>S) which was not detected in public or 1100 private exome databases. Expression of HDAC1 was reduced by 40% while expression of HDAC4, RAI1 and MBD5 in the proband's peripheral blood lymphocytes was normal.
Taken together, these data suggest that this novel HDAC1 mutation prevents transcription repression leading to autism, developmental delay and epilepsy in this patient. Direct DNA sequencing of gDNA from additional patients with autism +/- epilepsy and normal copy number state of HDAC1 is underway.

Genetic diagnosis in Intellectual Disability (ID) remains difficult because of the extreme genetic heterogeneity of this frequent condition. We report the case of a large 4-generation family with suggestive X-linked inheritance of ID (XLID), in which 20 members are affected, with moderate to severe ID and mild dysmorphic features in males, and behavioral phenotype in females. Standard cytogenetic and molecular investigations did not provide a diagnosis. A young patient of this family was included in a strategy of targeted high-throughput sequencing of 220 ID genes. It led to the identification of a novel missense mutation (c.6437C>G; p.Thr2146Arg) affecting a highly conserved residue in the *HUWE1* gene. We then showed its co-segregation with ID in 3 affected males and 3 obligate carrier females while it was absent in 3 unaffected males. Analysis of available DNA for others family members is ongoing. This missense predicted to be damaging (SIFT, Polyphen2), is absent from 10,563 chromosomes in the EVS database. Overlapping duplications including *HUWE1* have been found to segregate with ID in 12 families (Froyen et al.2012). Three missense mutations were also shown to segregate with ID in 3 families with probable or possible XLID, while a *de novo* missense was recently observed in a boy with autism spectrum disorder but not in his more mildly affected brother. It is therefore probable that the p.Thr2146Arg missense is causative of ID in this large family. A functional test of *HUWE1* activity on DNA repair is currently performed on patient's cells to confirm its pathogenicity.

Homozygosity mapping and exome sequencing approachs to find new gene(s) of recessive hydrocephalus

A. Drielsma[1], *M. Delaunoy*[1], *C. Perazzolo*[1], *J. Désir*[2], *N. Van Regemorter*[2], *I. Pirson*[1], *M. Abramowicz*[3];
[1]*IRIBHM-Université Libre de Bruxelles, Brussels, Belgium,* [2]*Department of Medical Genetics, Hôpital Erasme, Université Libre de Bruxelles, Brussels, Belgium,* [3]*Department of Medical Genetics and IRIBHM-Université Libre de Bruxelles, Brussels, Belgium.*

Background: Hydrocephalus is one of the commonest brain malformations. Its incidence is about 3 cases per 1000 live births. It is estimated that 40% of hydrocephalus would be of genetic origin. However, very few molecular causes are known. We recruit families with multiple cases of congenital hydrocephalus compatible with a recessive inheritance.
Here, we report a large family in which a consanguineous couple had five female fetuses with hydrocephalus identified during the second trimester of pregnancy. Affected fetuses presented with uni- to triventricular hydrocephalus and small cerebellum. Histology showed an opened aqueduct of Sylvius, ciliated ependymal cells and normal cortex architecture.
Material and methods: We perform homozygosity mapping with Affymetrix 250K Nsp chips, exome capture using NimbleGen SeqCap EZ Exome 60Mb and then we made an exome sequencing using Illumina HiSeq 2000. Mutations and family segregation are validated by Sanger sequencing.
Results: Homozygosity mapping defined three regions of interest. By exome sequencing, we identified a previously unreported homozygous two base-pair deletion in the last exon of the CCDC88C gene. This frameshift mutation p.E1949GfsX26 results in a premature stop codon. The mutation was homozygous in the affected foetuses and heterozygous in the parents and in both healthy sisters.
Conclusions: These results confirm that combination of homozygosity mapping and exome sequencing is a valuable tool to discover new genes. The development of next-generation sequencing will help to better understand brain malformations by uncovering the multiple genetic mechanisms.
Others patients are needed to find new genes.

P05.075

Hyperphosphatasia with Intellectual Disability (Mabry) Syndrome - two adult patients

L. Poelsler, *C. Fauth, B. Krabichler, B. Utermann, S. Tinschert, J. Zschocke;*
Division of Human Genetics; Medical University Innsbruck, Innsbruck, Austria.

The combination of persistent hyperphosphatasia, intellectual disability, neurologic deficits and epilepsy, and variable morphological anomalies was first described in 1970 by Mabry et al (OMIM #239300). It is caused by deficient synthesis of the glycosylphosphatidylinositol (GPI) anchor required for the attachment of cell-surface proteins to the plasma membrane and is inherited as an autosomal recessive trait. Causative mutations in two genes, *PIGV* and *PIGO*, have been identified. So far only children and adolescents have been reported in the literature.
We report here on two adult siblings of Austrian descent, a 34-year-old man (patient 1) and a 28-year-old woman (patient 2), who showed severe intellectual disability with very little speech development and hyperphosphatasia. Craniofacial features included macrocephaly, coarse facial features, arched eyebrows, up-slanting palpebral fissures, a broad nasal root, downturned corners of the mouth, a tented upper lip, and a bifid uvula. Their thumbs were broad and their fingers short, in particular the distal phalanges. Patient 2 had a short perineum. At the age of 8 months a febrile seizure was suspected in patient 2 and EEG abnormalities were detected; she did not have antiepileptic treatment in years and no further seizures occurred. Patient 1 never had seizures. Both patients showed a pronounced change in facial phenotype with age which lead to a coarsening of facial features.
The parents are distantly related and SNP-array analysis in patient 2 showed several regions of autozygosity, one of which included *PIGV* on chromosome 1. Results of molecular analyses are pending.

P05.076

A patient with cryptic interstitial 0.72-Mb deletion in the 22q13.2 region

R. Teek[1,2], *K. Simenson*[3], *K. Kuuse*[1], *E. Õiglane-Šlik*[2,4], *K. Õunap*[1,2];
[1]*Department of Genetics, United Laboratories, Tartu University Hospital, Tartu, Estonia,* [2]*Department of Pediatrics, University of Tartu, Tartu, Estonia,* [3]*Medical Faculty, University of Tartu, Tartu, Estonia,* [4]*Children's Clinic, Tartu University Hospital, Tartu, Estonia.*

The 22q13 deletion syndrome is characterized by intellectual disability (ID), developmental delay, speech deficit and hypotonia. Almost all of the published 22q13 deletions have been described as terminal. It is estimated that *SHANK3* gene, which maps to 22q13 region, is the major candidate gene for the neurologic features of the syndrome. Four cases with interstitial deletions of 22q13 are reported previously.
We report on a 7-year-old boy with ID, autistic behavior; abnormal EEG, spasticity and mild dysmorphic features included ptosis, facial asymmetry, prominent ears, clinodactyly of F5, T2-3 syndactyly. Patient also suffers from persistent urticaria with eosinophilia and elevated IgE level (2140 KU/L, normal<90). Chromosomal microarray analysis (HumanCytoSNP-12 BeadChip; Illumina Inc.) revealed a small interstitional *de novo* 0.72 Mb deletion in chromosomal region 22q13.2. This region harbors several known genes with different functions (*SREBF2, CYP2D6, NFAM1, TNFRSF13C*), but not *SHANK3* gene.Our patient has the smallest deletion among reported 22q13 region deletions and two copies of *SHANK3* gene. Our patient phenotype showed some differences in comparison with other patients with 22q13 de-

letion. Although he has ID and early childhood speech delay, he has normal growth parameters. In addition he has immune system dysfunction, which may be caused by a deletion of *TNFRSF13C* gene (related to immune system dysfunction) or *NFAM1* gene (cause atopic dermatitis and high IgE levels). It has been previously supposed that 22q13 deletion syndrome may be associated with immune system dysfunction in addition to neuropsychiatric disorders.

Intellectual deficiency (ID) is a public health problem concerning 1 to 3% of children. ID is clinically and genetically heterogeneous, and can be divided into non-syndromic- (isolated) and syndromic forms when associated with other features. We report a 5-year-9-month-old girl born to first-cousin parents after an uneventful pregnancy. She presented with psychomotor delay (walking achieved at 2.5 years), ID, behavioural troubles (hyperactivity, stereotypies, sleep disorders), speech defect, postnatal microcephaly, and spasticity of lower limbs. Brain MRI showed corpus callosum and vermis hypoplasia, and moderate bilateral symetric leucopathy. Microarray analysis revealed an intragenic duplication of the TRAPPC9 gene in the 8q24.3 region. qPCR identified 4 copies of the microrearrangement as well as an heterozygous status for the duplication in both parents. TRAPPC9 encodes for a protein involved in intracytoplasmic vesicular transport with a wide tissular expression. TRAPPC9 mutations have been reported in non-syndromic ID patients from consanguineous families, with features similar to those observed in our patient. These mutations could represent a frequent cause of autosomal-recessive ID when associated with postnatal microcephaly, behavioural troubles, and corpus callosum anomalies. Although point mutations have often been published, to our knowledge, this is only the second report of a microrearrangement of the TRAPPC9 gene, which may be responsible for autosomal-recessive ID (first case: homozygous 8q24.3 microdeletion). In a attempt to delineate a specific phenotype suggesting a TRAPPC9 alteration, we reviewed the patients reported in the literature.

P05.079

Molecular characterization of a patient suffering Intellectual Disability.

I. Navarro Vera[1], *S. Ciria Abad*[1], *M. Cristina*[1], *R. Marín*[2], *P. Madero Barrajón*[1];
[1]*Centro de Análisis Genéticos, Zaragoza, Spain,* [2]*Hospital Puerta del Mar, Cádiz, Spain.*

Introduction: Intellectual disability is of major concern troughout the world. In 40% of the cases etiology remains unknown.
Here we present a four years old girl showing psychomotor retardation, language difficulty and dismorphic features. Parents were non consanguineous and healthy. In all of them, kariotype was normal, at 550 level banding GTG. We performed MLPA analysis in order to detect possible subtelomeric rearrangements, and confirmed our results by FISH.
Methods: MLPA analysis were performed using the SALSA P036 Human Telomere-3 containing one probe for each subtelomeric region from chromosome 1-22 and the two X/Y pseudoautosomal regions and SALSA P286 containing eight probes specific for the 10q26.3 region (MRC Holland, Amsterdam, The Netherlands). Fluorescence in situ hybridization (FISH) with subtelomeric probes (Kreatech) were carried out.
Results: MLPA analysis with SALSA P036 showed evidence of a deletion in the terminal region of chromosome 10q (probe PAOX gene in 10q26.3). Further analysis with SALSA P286 showed a deletion from at least 5.44Mb in 10q26.3 involving all eight probes located in this region. FISH using probes 10pter (D10S2488) and 10qter (D10S2290) confirmed this deletion detected by MLPA in the index case and showed normal patterns in her parents, determining it was a *de novo* alteration.
Conclusion: This study confirms that the combination of MLPA analysis and FISH still allows to resolve cases, where the genetic causes of the clinical features remain unexplained.

P05.080

Distal 16p11.2 duplication in two patients with intellectual disability

C. Pagan, *S. Drunat, L. Perrin, C. Dupont, B. Benzacken, A. Verloes, A. Tabet;*
Department of Genetics - Robert Debré Hospital - APHP, Paris, France.

Several recurrent rearrangements have been described at 16p11.2 locus. Deletions and duplications of a proximal 600 kb region (29.5-30.1 Mb) have been associated with autism, intellectual disability, schizophrenia, and mirror metabolic phenotypes. In addition, deletions of an adjacent, distal 200 kb region (28.7-28.9 Mb) have been associated with obesity and developmental delay. Here we describe two male patients presenting with mental retardation and carrying the reciprocal distal 16p11.2 duplication, identified by whole genome SNP array (HumanCytoSNP-12, Illumina) in one case and CGH-array (Agilent, 180K) in the other one.
The first patient displayed intellectual disability, motor delay, attention deficit, dysmorphic features and dextrocardia. He had average height and weight. The duplication (200 kb, 28.7-28.9 Mb) was inherited from his father. The second patient presented with intellectual disability, severe language delay, mild hand tremor but without dysmorphic features. His height was average, and his weight within low normal range (10th percentile). The duplication (285 kb, 28.7-29.0 Mb) was inherited from his mother, while there was a marked history of language disorders for his father and paternal family.
These two observations suggest that the distal 16p11.2 duplication may be a risk factor for intellectual disability. One or few genes included in the duplicated region could be dosage sensitive. However, it is likely that undetermined, additional hits contribute to the phenotype of these patients, as indicated by the transmission of the duplication by an unaffected parent, the informative family history of the second patient, and the phenotypic differences between the two patients.

P05.081

Clinical and cytogenetic features of Smith Magenis and Potocki-Lupski syndromes: about two Tunisian cases

H. Ben khelifa[1], *N. Soyah*[2], *I. Ben Abdallah*[1], *A. Labalme*[3], *D. SANLAVILLE*[3], *H. ELGHEZAL*[1], *S. MOUGOU-ZRELLI*[1], ***A. SAAD***[1];
[1]*laboratory of cytogenetics,molecular genetics and reproductive biology - Farhat Hached hospital, sousse, Tunisia,* [2]*pediatrics department Farhat Hached Hospital, sousse, Tunisia,* [3]*laboratory of cytogenetics,CBPE - Bron, Lyon, France.*

Smith Magenis (SMS) and Potocki Lupski (PTLS) syndromes have long been known to display specific neurobehavioral traits. These syndromes are two examples of Contiguous Gene Syndrome that are associated with a microdeletion and microduplication respectively within chromosome 17 band p11.2. The dosage sensitive gene responsible for most phenotypes in SMS has been identified: the Retinoic Acid Induced 1 (*RAI1*).
Studies on mouse models and humans suggest that *RAI1* is likely the dosage sensitive gene responsible for clinical features in PTLS.
We carried out a complete cytogenetic analysis for two Tunisian patients screened for craniofacial anomalies, intellectual disability and behavioral disorders with a diagnosis of SMS and PTLS syndromes. RHG banding analyses were normal. Whole genome analysis with the Agilent Human Genome CGH Microarray Kit 180K proceeded on our patients' DNAs revealed de *novo* 3,5 Mb microdeletion and 7,5 Mb microduplication on chromosome 17p11.2 encompassing OMIM genes especially Retinoic Acid Induced 1 Gene (*RAI1*). The confirmation and parents'analysis were performed by fluorescent *in Situ* hybridation (FISH).
In the present study, the karyotype's level of resolution did not achieve to detect these aberrations. However, the whole genome coverage provided by high resolution level technique as array CGH has displayed these micro imbalances and achieved to delineate the breakpoints. This highlights the effectiveness of this microarray which overcomes the standard karyotype.
So, our results enable us to discuss the role of the microarrays' spot in cytogenetic laboratories and whether it can replace the standard karyotype.

Contribution of copy number variants (CNVs) in congenital unexplained intellectual and developmental disabilities in 149 patients: the first Lebanese study leading to new findings in CNVs

N. Alam Choucair[1], *J. Abou Ghoch*[1], *L. Villard*[2], *A. Mégarbané*[1,3], *E. Chouery*[1];
[1]*University of Saint-Joseph, Beirut, Lebanon,* [2]*University of Aix-Marseille II, Marseille, France,* [3]*Institut Jérôme Lejeune, Paris, France.*

Purpose: Molecular karyotyping is nowadays the most adopted clinical test for patients with unexplained intellectual disability (ID) and developmental delay (DD). This study exposes the strategy and the conditions of analysis leading to the determination of causative copy number variants (CNVs). It also presents de novo pathogenic CNVs and reviews for several described ones.
Methods: We have applied whole-genome technique to a cohort of 149 lebanese patients with ID/DD using the 2.7M array of Affymetrix. Confirmation of array findings was performed using quantitative PCR. Bioinformatical and statistical analysis were used in order to reduce false positive CNVs.
Results: Criteria were set to improve the reliability of CNVs. When the latter is greater than 62 Kb and contains at least 49 markers it is then considered as certainly existing.
14.8% abnormalities in 149 Lebanese ID/DD patients were detected, of which 15 aberrations overlapped known causative CNVs and 7 potentially pathogenic.
A database of copy number polymorphisms was constructed displaying CNVs carried by 30 healthy individuals.
Conclusion: This is the first Lebanese whole genome study of ID/DD patients. It has shown the importance of uncovering genomic imbalances in the diagnostic and research approaches. All CNVs found will be a guide to clinicians, helping them in the diagnosis of further cases.

EPHA1 C1475T and C1891T polymorphisms in Ukrainian patients with idiopathic intellectual disability

R. V. Gulkovskyi[1,2], *G. M. Bychkova*[3], *S. A. Kravchenko*[1], *N. V. Hryshchenko*[1], *S. Y. Chernushyn*[1], *M. Nõukas*[4], *M. Sauk*[4], *L. Milani*[5], *T. Pippucci*[6], *F. Balombo*[6], *C. Graziano*[6], *L. A. Livshits*[1];
[1]*Institute of Molecular Biology and Genetics of National Academy of Sciences of Ukraine, Kyiv, Ukraine,* [2]*Taras Shevchenko National University of Kyiv, Educational and Scientific Centre „Institute of Biology", Kyiv, Ukraine,* [3]*Research Centre for Radiation Medicine, NAMS of Ukraine, Kyiv, Ukraine,* [4]*Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia,* [5]*Estonian Genome Center, Tartu, Estonia,* [6]*U.O. Genetica Medica, University of Bologna, Bologna, Italy.*

Exome analysis of an Ukrainian family with healthy unrelated parents and two brothers affected by Intellectual Disability (ID) revealed several variants in either homozygous or compound heterozygous state in five genes. Among these genes, we decided to concentrate on the *EPHA1* gene, where C1475T (maternal) and C1891T (paternal) substitutions were detected in both patients. *EPHA1* is an ephrin receptor gene, highly expressed in the human brain, and it seemed a good candidate for ID.
The proband is a 12 year old boy with ID (IQ=43) and hyperactivity. His brother is a 4 year old boy with febrile convulsions, ID and multiple congenital anomalies. Standard karyotype, molecular analysis of *FMR1* gene and array-CGH analysis (400K) were normal in both patients.
We further investigated the possible role of *EPHA1* gene variants in severe ID. Case-control study included 51 patients with severe ID and 186 individuals as a population control. We performed a screening of the two variants through PCR-RFLP (C1475T) and allele-specific PCR (C1891T). The *EPHA1* 1475T allele frequency was significantly higher in ID patients (2,9%) as compared to controls (0,5%). *EPHA1* 1891T variant was found neither in the control group, nor in ID patients. These preliminary results indicate a possible association between *EPHA1* variants and ID among Ukrainian patients. Further studies (especially the complete sequencing of *EPHA1* coding exons) will be conducted to confirm the involvement of *EPHA1* mutations in ID development. This study was supported by EC FP-7, CHERISH project no. 223692.

P05.084

Loss of FMR2 further emphasises the link between deregulation of immediate early response genes FOS and JUN and intellectual disability

L. Nguyen[1], *M. Melko*[2,3,4], *M. Shaw*[1], *L. Jolly*[1], *B. Bardoni*[2,3,4], *J. Gecz*[1,5];
[1]*School of Paediatrics and Reproductive Health, The University of Adelaide, North Adelaide, Australia,* [2]*Institut de Pharmacologie Moléculaire et Cellulaire, CNRS UMR 7275, Nice, France,* [3]*Faculté de Médecine, Université de Nice-Sophia Antipolis, Nice, France,* [4]*CNRS LIA "Neogenex", Valbonne, France,* [5]*Department of Genetics Medicine, SA Pathology, Adelaide, Australia.*

Loss of FMR2 causes Fragile X E (FRAXE) site associated intellectual disability (ID). FMR2 regulates transcription, promotes alternative splicing with preference for G-quartet structure harbouring exons, and is localised to the nuclear speckles. In primary skin fibroblasts from FRAXE patients (n=8), we found a significant reduction in the number but a significant increase in the size of nuclear speckles, when compared to the controls (n=4). Since nuclear speckles are enriched with factors involved in pre-mRNA processing, we explored the consequence of these defects and the loss of FMR2 on the transcriptome. We performed whole genome expression profiling using total RNA extracted from these cell lines and found 27 genes significantly deregulated by at least 2-fold at $P < 0.05$ in the patients. Among these genes, FOS was significantly upregulated and was further investigated due to its established role in neuronal cell function. We showed that i) 30% depletion of Fmr2 in mouse primary cortical neurons led to a 2-fold increase in Fos expression, ii) overexpression of FMR2 significantly decreased FOS promoter activity in luciferase assays, and iii) as FOS promoter contains a serum response element, we found that not FOS, but JUN, which encodes for a protein that forms a transcriptional activator complex with FOS, was significantly upregulated in the patients' cell lines upon mitogen stimulation. These results suggest that FMR2 is an upstream regulator of FOS and JUN, and further link deregulation of the immediate early response genes to the pathology of ID and FRAXE associated ID in particular.

Familial intellectual disability in Brazilian institutions

A. F. Maris[1], *I. T. Barbato*[2], *J. H. Barbato*[2,3], *G. R. de Luca*[3], *L. F. de Oliveira*[1], *L. S. Linhares*[1], *N. Baretto*[1], *N. Rigobeli*[1];
[1]*Universidade Federal de Santa Catarina, Florianópolis, SC, Brazil,* [2]*Neurogene, Florianópolis, SC, Brazil,* [3]*Hospital Infantil Joana de Gusmão, Florianópolis, SC, Brazil.*

We present the results of the first part of a project whose main purpose is to understand the relevance of familial intellectual disability among the population of individuals with moderate to severe intellectual disability who attend special day care institutions.
For this purpose we developed a survey instrument which was applied by members of our team to the guardians of 800 familial intellectual disability individuals in SC, Brazil, to select the families where two or more individuals in three generations have familial intellectual disability. Possible familial cases were selected to proceed to the second part of this project (collect family history to validate the data, try to clarify diagnostics).
Findings of our survey indicate:
1) Etiology: 14% with Down Syndrome; 3% due to infectious diseases (meningitis, rubella, toxoplasmosis, cytalomegalovirus and others; 1.5% due to known monogenic causes, 0.8% with known microdeletion/duplication syndromes and about 1% with known syndromes of unclear cause. Cerebral palsy was reported for 11% of the cases, most of them attributed to neonatal oxygen deprivation.
2) Other cases in the family: 52.5% reported other cases, 8% of which were obviously not related, leaving 39.5% of potential familial cases to proceed to the next part of our project. Of those, 16% had 2 cases; 10% had 3 cases; 14% had 4 or more cases (20% of those with 7 to 14 affected individuals). Even if many cases may show to be unrelated, the numbers are astonishing. This is the first survey of this kind we know.

P05.086

Analytical & clinical performance assessment of the Affymetrix CytoScan® Dx cytogenetic microarray system

R. Pfundt[1], *K. Kwiatkowski*[2], *A. Chaubey*[3], *A. Roter*[2], *S. Close*[4], *J. Reiswig*[2], *E. Thorland*[5], *R. Hockett*[6], *E. T. Fung*[2];
[1]*Radboud University Medical Centre, Nijmegen, Netherlands,* [2]*Affymetrix, Santa Clara, CA, United States,* [3]*Greenwood Genetic Center, Greenwood, SC, United States,* [4]*GenEngine, Fishers, IN, United States,* [5]*Mayo Clinic, Rochester, MN, United States,* [6]*CombiMatrix Diagnostics, Irvine, CA, United States.*

Identification of pathogenic copy number variants (CNVs) by cytogenetic microarrays has demonstrated a higher diagnostic yield as compared to conventional methods, such as karyotyping and FISH. This study's objective was to characterize analytical and clinical accuracy of CytoScan Dx compared to routine patient care (RPC) in surplus samples from a post-natal population exhibiting developmental delay, intellectual disability, congenital anomalies/dysmorphisms. Samples were collected consecutively at 3 sites where RPC comprised of one or more methods (karyotyping/FISH/microarray) for establishing a copy number call (excluding Affymetrix arrays). An independent cytogeneticist (with no previous patient information) interpreted the samples processed at one site on CytoScan Dx.

960 samples were analyzed. RPC reported 425 CNVs. Analytical accuracy was calculated as the percentage of RPC-identified regions that were corroborated by CytoScan Dx. Excluding 12 RPC-reported regions below the reported resolution of CytoScan Dx, the analytical accuracy of CytoScan Dx as compared to RPC was 97.3% (95% CI = 95.3-98.5%, 402/413 CNVs). The average percent CNV overlap between RPC and CytoScan Dx was 92.8%±11.23. Of the 402 samples that agreed analytically, 67.4% had the same interpretation.

To date, this data represents the largest clinical study assessing both the analytical and clinical accuracy of CytoScan® Dx as compared to RPC and validates the high analytical accuracy of CytoScan® Dx. Differences in clinical interpretation are expected as they are influenced by many factors including availability of clinical information, parental results, and the time period of evaluation, since the body of literature regarding the pathogenicity of CNVs continues to evolve.

Clinical description of a female patient with a mutation in *WRD45*, a gene involved in a new X-linked NBIA (neurodegeneration with brain iron accumulation)

C. Mignot[1,2,3], *A. Gregory*[4], *P. Hogarth*[4], *L. Sanford*[4], *S. Hayflick*[4], *D. Héron*[1,2];
[1]*APHP, Groupe Hospitalier Pitié Salpêtrière, Department of Genetics, Paris, France,* [2]*Referral Center for Rare Genetic Intellectual Disabilities, Paris, France,* [3]*APHP, Hôpital Armand Trousseau, Neuropediatric Unit, Paris, France,* [4]*Oregon Health & Science University, Portland, OR, United States.*

Neurodegeneration with brain iron accumulation (NBIA) is a group of diseases characterized by the accumulation of iron in the basal ganglia. Six genes are presently involved in NBIA presenting in childhood/adolescence, each of them having particular clinical and/or radiological features. We report the clinical history of a young adult patient with a disease history suggestive of SENDA syndrome (static encephalopathy with neurodegeneration in adulthood), now called BPAN syndrome.

A diagnosis of epilepsy and global developmental delay was made at first examination at 22 months. The evolution was characterized by: 1) easy epilepsy control with anti-epileptic drug, 2) severe intellectual deficiency that became obvious during the first years of life (independent walking achieved at 2 years, absence of language, limited communication skills) associated with stereotypies and unmotivated laughters, 3) facial dysmorphism with body asymmetry, 4) the apparition of pyramidal signs with walking difficulties after puberty, 5) an OFC growing on the -2SD curve.

Brain MRI showed at the age of 16 years a heterogeneous signal of the pallidum on T1-weighted images and a hyposignal of the pallidum and locus niger on T2-FLAIR-weighted images. *PLA2G6* mutations were ruled out. The c.56-1G>A splice-site mutation not found in the proband's mother was identified in *WDR45.*

Clinical and radiological characteristics in our patients are consistent with the diagnosis of SENDA/BPAN syndrome and with those of other patients with mutation in *WDR45*. Though the initial clinical picture suggested an atypical form of Rett syndrome, brain MRI features only guided the etiogogical diagnosis.

Phenomic clues to genomic variation in patients with developmental delay or intellectual disability

E. Preikšaitienė[1,2], *A. Molytė*[1], *Z. Ciuladaite*[1,2], *J. Kasnauskiene*[1], *A. Utkus*[1,2], *V. Kučinskas*[1,2];
[1]*Dept. Human and Medical Genetics, Vilnius University, Vilnius, Lithuania,* [2]*Centre for Medical Genetics, Vilnius University Hospital Santariskiu Clinics, Vilnius, Lithuania.*

Background and aims. Unless high-resolution microarray technologies have been recommended as the first-tier cytogenetic diagnostic test for patients with developmental delay/intellectual disability (DD/ID), still not every laboratory has possibilities to perform this analysis to every patient with DD/ID. Our aim was to determine whether patients with pathogenic copy number variants (pCNVs) are confident to a distinct clinical subgroup.
Method. Retrospective review of clinical and molecular karyotyping data of 211 patients was performed. Clinical data of patients with chromosomal alterations (n=29) were compared with those without pCNVs (n=182).
Results. The findings indicate the increased frequency of pCNVs in patients with syndromic DD/ID (p=0.018), at least one congenital anomaly (p=0.005), three and more minor anomalies (p=0.016), congenital malformations of CNS (p=0.026), congenital malformations of musculosceletal system (p=0.037) and minor anomalies of eye, ear, face and neck subgroup (p=0.003). Statistically significantly several phenotypic traits were more frequent in patients with pCNVs, as hydrocephalus (p=0.023), congenital malformations of corpus callosum (p=0.014), downward slanting palpebral fissures (p=0.008), minor anomalies of ear (p=0.002), micrognathia (p=0.004), brachydactyly (p=0.005), umbilical hernia (p=0.008). *Café au lait* spots more frequently were in patients without pCNVs (p=0.023). A multivariate logistic regression analysis was performed to determine the predictors of pCNVs. Three independent predictors of pCNVs were determined: congenital malformations of corpus callosum, minor anomalies of ear and brachydactyly, increasing the risk of pCNVs by 0.1, 3.3 and 7.5 times respectively.
Conclusions. Our results suggest, that clinical features, as syndromic DD/ID, specific congenital and minor anomalies might be possible indicators for pCNVs.

P05.089

A wide spectrum of intellectual disability in two siblings with a 6p22.3-p23 microdeletion encompassing JARID2

A. C. Foster, *G. K. Hall, F. S. Togneri, D. McMullan, T. Cole;*
Birmingham Women's Hospital, Birmingham, United Kingdom.

Interstitial deletions of 6p22-6p24 are associated with a variable phenotype including intellectual disability, autistic spectrum disorder, hypotonia and congenital abnormalities. There are many potential disease-causing genes in this region, including JARID2, DTNBP1, ATXN1, and MYLIP, and delineating genotype-phenotype correlations has been a challenge. It has been suggested that deletions of JARID2, a DNA-binding transcriptional repressor expressed in embryonic and adult neurones, are associated with a characteristic facial appearance as well as intellectual disability.

Our first patient presented with mild to moderate learning disability and some Marfanoid systemic features, scoring 6/20 on the revised Ghent criteria. Cardiac and ophthalmic investigations were normal. CGH microarray identified a 1.2Mb microdeletion on chromosome 6p22.3-p23 involving JARID2 and DTNBP1 only; targeted microarray and FISH studies did not identify this deletion or a predisposing rearrangement in either parent. The patient's younger brother presented with much more severe learning disabilities and autistic spectrum disorder. He had no similar skeletal features but both boys had similar prominent supraorbital ridges. Investigation with CGH microarray found the same microdeletion, suggesting low level somatic-gonadal mosaicism or true gonadal mosaicism as a cause for the two affected siblings.

This case illustrates the wide spectrum of learning difficulties and behavioural difficulties that may be seen even in siblings with identical small microdeletions in this region. This may represent a challenge to the establishment of a clinically recognisable phenotype for JARID2 deletions and highlights the complexity of the genetic aetiology of intellectual disability.

Further delineation of medical and behavioural aspects of the KBG syndrome caused by *ANKRD11* mutations

C. W. Ockeloen[1], *M. H. Willemsen*[1], *S. de Munnik*[1], *B. B. van Bon*[1], *A. Verrips*[2], *H. IJntema*[1], *N. de Leeuw*[1], *C. C. van Heumen*[1], *C. E. Carels*[1], *T. Kleefstra*[1];
[1]*Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands,* [2]*Department of Paediatric Neurology, Canisius Wilhelmina Hospital, Nijmegen, Netherlands.*

Introduction Recently *ANKRD11* mutations were identified as the cause of KBG syndrome, an autosomal dominant intellectual disability (ID) syndrome with specific dental, craniofacial and skeletal anomalies. To further expand the phenotypic spectrum and knowledge on medical and behavioural management, we present a comprehensive overview of clinical and molecular characteristics of nine so far unreported cases from five different families with *ANKRD11* aberrations.
Methods Clinical features of nine cases with KBG syndrome were evaluated and a review of the existing literature on KBG syndrome was performed. Sequence analysis of the *ANKRD11* gene was performed using Sanger sequencing. An Affymetrix CytoScan HD array was used according to the manufacturer's protocol.
Results In the first family a heterozygous frameshift mutation in *ANKRD11* was identified in four affected children as well as their mother. Three other isolated KBG syndrome patients all harboured frameshift mutations in *ANKRD11*. Microarray analysis revealed a 100 kb deletion encompassing exons 1-3 of the *ANKRD11* gene in one patient.
Discussion Hallmark characteristics of KBG syndrome are mild to moderate ID, macrodontia and other dental anomalies, skeletal anomalies, short stature and typical dysmorphic features. Less common features are heart defects, palatal defects, hearing loss, ophtalmologic abnormalities and central nervous system involvement. Neurobehavioural problems, especially autism spectrum disorder and attention deficit hyperactivity disorder, are often present but gained less attention so far in medical literature. However, we observed that these can be severe and require adequate management. Better recognition, a multidisciplinary approach and early intervention are essential to patients and their families.

Exome Sequencing assesses the role of the KIAA2022 gene in the aetiology of X-linked intellectual disability

M. Rio[1,2], *S. Moutton*[2], *A. Mazery*[1], *C. Bole-Feysot*[3], *P. Nitschle*[3], *N. Bahi-Buisson*[4], *A. Munnich*[1,2], *L. Colleaux*[2];
[1]*Departement de Génétique, Hôpital Necker, APHP, Paris, France,* [2]*INSERM781, Université Paris Descartes, Paris, France,* [3]*Plateforme Génomique, Institut IMAGINE, Université Paris Descartes, paris, France,* [4]*Departement de Neuropédiatrie, Hôpital Necker, APHP, paris, France.*

Here we report on the clinical and molecular characterisation of an X-linked intellectual disability (XLID) family ascertained by next-generation sequencing (NGS) of most of the X-chromosome transcripts. Two brothers were referred for genetic work up because of intellectual disability. The youngest presented with severe intellectual disability, seizures and hyperactivity. The elder brother was highly social, communicated verbally with good sentence structure and was able to read and write. His IQ was 50. Their 38 years old maternal uncle was unemployed, unable to read and write and his IQ was 46. All of them had normal neurological examination and no remarkable facial features were present. The two affected sibs were tested using the XSeq ™ Research Screening Panel developed by Raindance Technologies. The two brothers shared only 3 previously unreported variants, two misseense variants in DMD and PLP2 gene and one frameshift variant in KIAA2022 gene. Additional analysis showed that only the KIAA2022 mutation segregated with known carrier status and in all affected individuals. Interestingly, disruption of this gene have previously been identified in two mentally boys and this gene is highly expressed in fetal brain and the adult cerebral cortex. Our data confirm the role of the KIAA2022 gene in the aetiology of intellectual disability and the interest of NGS in small XLID families.

The common polymorphism of the KIBRA gene is associated with academic achievement

I. A. Alexeev[1], *L. M. Sungatullina*[2], *E. S. Nasibulina*[1], *A. S. Kruchkov*[3], *I. I. Ahmetov*[1];
[1]*Kazan State Medical University, Kazan, Russian Federation,* [2]*Kazan Federal University, Kazan, Russian Federation,* [3]*Russian State University of Physical Education, Sport, Youth and Tourism, Moscow, Russian Federation.*

The KIBRA protein is assumed to play an important role in synaptic plasticity. Genetic variation at the KIBRA gene rs17070145 polymorphism has been linked to episodic memory and executive function. T allele carriers of SNP rs17070145 have been reported to outperform individuals that are homozygous for the C allele in episodic and working memory tasks. Since academic achievement is directly related to the memory, we hypothesized that the KIBRA T allele could be associated with the ability to get a higher education and a PhD degree. We have tested this hypothesis in three groups of the Russian population (n=98; all Caucasians): primary school-aged children, students of universities and PhD degree holders. The frequencies of the T allele and TT genotype in the Russian children were similar with those reported in the European populations (T allele: 29.0% and 31.9%; TT genotype: 9.7% and 10.6%, respectively). We found an increasing linear trend of T allele with increasing academic level of individuals (children - 29.0%, students - 37.7%, PhD degree holders - 64.3%; P=0.0032). Interestingly, the frequency of the T allele in students willing to apply for a PhD in future was higher (54.5% vs. 33.3%; P=0.08) in comparison with unwilling students. Compared with CC homozygotes, the odds ratio of being a PhD holder in TT homozygotes was 12.44 [95% CI: 1.995-77.632, P=0.0108]. In conclusion, our results suggest that the rs17070145 C/T polymorphism of the KIBRA gene seems to be associated with academic achievement, with the T allele exerting a beneficial effect.

Brain imaging in Klinefelter syndrome (47, XXY)(KS), a genetic disorder characterized by the presence of an extra X chromosome, may contribute to understanding the relationship between gene expression, brain structure, and subsequent cognitive disabilities and psychiatric disorders.
We conducted the largest to date voxel-based morphometry study of 65 KS males and 65 age- and educational-matched male controls and correlated these data to neuropsychological test scores. The KS males had significantly smaller total brain volume (TBV), total gray matter volume (GMV) and total white matter volume (WMV) compared to male controls, whereas no volumetric difference in cerebral spinal fluid (CSF) was found. There were no differences in TBV, GMV, WMV or CSF between testosterone treated KS (T-KS) and untreated KS (U-KS) males. Compared to male controls, KS males had significantly decreased GMV bilaterally in insula, putamen, caudate, hippocampus, amygdala, temporal pole and frontal inferior orbita. Additionally, right parahippocampal region and cerebellum was reduced in KS males. KS males had significantly larger volumes in right postcentral gyrus, precuneus and parietal regions. Multivariate classification analysis discriminated KS males from male controls with 96.9 % ($p<0.001$) accuracy. Regression analyses, however, revealed no significant association between GMV differences and cognitive and psychological factors within the KS males and male controls or the groups combined. These results show that although gene dosage effect of having and extra X-chromosome may lead to large scale alterations of brain morphometry and extended cognitive disabilities no simple correspondence links these measures.

Transcriptome sequencing in patients with Koolen-de Vries syndrome

*K. Neveling, E. Verwiel, P. de Vries, B. B. A. de Vries, J. A. Veltman, **D. A. Koolen**; Radboud University Medical Centre, Nijmegen, Netherlands.*

The Koolen-de Vries syndrome is a multisystem disorder characterized by intellectual disability (ID), hypotonia, epilepsy, distinctive facial features, and congenital malformations of the heart, urogenital tract and central nervous system. The syndrome is also known as 17q21.31 microdeletion syndrome, due to typical microdeletions that can cause the phenotype. Recently, we and others showed that haploinsufficiency of *KANSL1* is sufficient to cause the syndrome. The *KANSL1*-gene encodes a chromatin-modifying protein that is a member of the nonspecific lethal complex. This complex contains, among other proteins, the acetyltransferase KAT8, which influences gene expression through acetylation of H4K16 and p53.

To investigate the effect of *KANSL1* mutations on genome-wide expression levels, we performed transcriptome sequencing of twelve different samples from patients with Koolen-de Vries syndrome. The mutations in these samples comprise six classical 17q21.31 microdeletions, two atypical deletions, three *KANSL1* point mutations and one so far unidentified mutation. Enrichment of mRNA was done using the MicroPoly(A)Purist Kit (Ambion), whole transcriptome library preparation was performed using the SOLiD Total RNA-Seq Kit (STaR Kit, Life Technologies) and paired-end sequencing was performed on a 5500XL sequencer (Life Technologies). The expression levels of these trancriptomes were compared to expression levels of eight healthy controls and functional annotation clustering of differentially expressed genes was done using the Database for Annotation, Visualization and Integrated Discovery (DAVID).

We have detected new genes that are differently regulated in the 17q patients compared to controls. Further investigation of these genes might give new insights into the pathways that are underlying ID.

Learning disabilities (LD) are a clinically and genetically heterogeneous group of disease. The identification of familial cases of clinically homogeneous endophenotypes of LD might help the management of the patients, and precise the genetic counselling, Array-CGH and high-throughput sequencing dramatically expand the number of genes implicated in isolated ID, highlighting the implication of neuron specific post-mitotic transcription factors and synaptic proteins as candidate genes. We report on a unique family diagnosed with a 6p21 microdeletion segregating in 3 patients with learning disability of autosomal dominant heredity. Neuropsychological assessment identified a selective deficit of working memory, without ID in the patients. Further investigations identified a defect in the executive functions, and auditoro-verbal processes. These data were consistent with brain MRI and FDG-PET functional brain imaging that revealed atrophy and hypometabolism of cerebral region strongly implicated in working memory processes when compared to controls. The 870kb microdeletion encompassed 3 genes with only one brain expressed gene encoding for a postsynaptic protein named LRFN2/SALM1. We performed an immuno-colocalization with electronic microscopy demonstrating the tight co-localization of LRFN2/SALM1 with the NMDA (N-Methyl-D-Aspartate) receptors in the lateral part of the postsynaptic density of cerebellar and hippocampal rat neurons. Altogether, the combined approaches highlighted the implication of LRFN2/SALM1 in LD, specifically by its implication in working memory processes and executive functions. A medication by NMDA modulator could be discussed because of the interaction of LRFN2/SALM1 with the NMDA receptors.

Migrating partial seizures of infancy (MPSI) is a rare epileptic encephalopathy characterized by i) seizure starting during the first months, ii) focal seizures randomly migrating from one cortical region to another, iii) arrest of psychomotor development with a severe cognitive and motor outcome and acquired microcephaly. We identified de novo *KCNT1* mutations in 6/12 patients with MPSI. *KCNT1* encodes a sodium-activated potassium channel. We showed that MPSI-associated mutations are located in the C-terminal domain of KCNT1 and cause a gain of function.

We analyzed *KCNT1* sequence in 16 additional patients with MPSI and in a cohort of 14 patients with infantile multifocal epilepsy (IME), a rare epilepsy syndrome of infancy sharing with MPSI

early onset, drug-resistance and severe cognitive outcome.

We found four novel de novo mutations in MPSI patients, all mapping within the C-terminal domain. In two MPSI brothers, an inherited mutation from the unaffected father raises the issue of genetic counseling. Genotype-phenotype correlation revealed no differences between *KCNT1* positive and negative MMPSI cases regarding age of onset, pharmacoresistance, cognitive or motor outcome. *KCNT1* sequencing revealed no mutations in patients with IME.*KCNT1* mutations are found in 43% of cases (12/26) of

MPSI confirming *KCNT1* as the major disease-causing gene in this syndrome. Absence of KCNT1 mutation in IME may suggest a specific link between KCNT1 and the «EEG migrating pattern »

phenotype and confer to the genetic testing of *KCNT1* a diagnostic value in the context of neonatal pharmacoresistant epilepsy with severe delay.

Characterization of supernumerary marker chromosomes by high resolution array CGH

R. V. Vazharova[1], *I. Bradinova*[1], *S. Andonova*[1], *S. Bichev*[1], *V. Bojinova*[2], *V. Stoyanova*[3], *A. Savov*[1], *I. Kremensky*[1];

[1]National Genetic Laboratory, Sofia, Bulgaria, [2]USBALNP „Saint Naum", Sofia, Bulgaria, [3]Department ot Pediatrics and Medical Genetics, Medical University – Plovdiv, Plovdiv, Bulgaria.

Background: Small supernumerary marker chromosomes (sSMC) are described as small structurally abnormal chromosomes that occur in addition to the normal 46 chromosomes. The phenotypes associated with the presence of a marker vary from normal to severely abnormal. The rate of sSMC among patients with mental retardation (MR) is estimated to be about 0.288%. In a series of 165 patients with MR/developmental delay we found 3 with de novo sSMC by conventional GTG karyotyping.
Aim: The aim of the study was to clarify the chromosome origin of the supernumerary markers and to map the chromosome regions with aberrant copy number.
Materials & methods: Array CGH analysis was performed using custom designed whole-genome oligonucleotide arrays (OGT, UK) with a median probe spacing of about 2.5 kb and median resolution of about 10 kb. CytoSure Interpret (OGT, UK) software was used for CNV detection.
Results & discussion: The supernumerary marker chromosomes are found to originate from chromosomes 18 (arr 18p11.32p11.21(123,155-15-,065,191)x5), 15 (arr 15q11.2q13.3(18,410,710-30,678,185)x4) and 20 (arr 20q13.33(60,446,113-62,382,429)x4), respectively. Clinical presentation of the patients and some specific symptoms correlated well to the chromosomal abnormalities found. We concluded that molecular techniques such as arrayCGH, associated to cytogenetic methods can help in detecting genomic imbalances and unraveling the genes involved in the phenotype variability of patients with supernumerary marker chromosomes. Furthermore, the molecular characterization of the alterations found provides valuable information for the follow-up of the patients and genetic counseling of their families.

Just recently, partial or complete deletion of methyl-CpG-binding domain 5 (MBD5) gene has been implicated as causative in the phenotype associated with 2q23.1 microdeletion syndrome. The core phenotype observed includes intellectual disability (ID), seizures, significant speech impairment and autistic-like symptoms. In the course of systematic whole-genome screening of individuals with unexplained ID by array-based comparative genomic hybridization, we identified de novo intragenic deletions of only the 5'-non-coding region of MBD5 in three patients leading, as previously documented, to haploinsufficiency of MBD5. In addition, we described two patients with two different unreported MBD5 intragenic duplications. The first one leads to the presence of numerous aberrant transcripts with premature termination codon. The second one is inherited from a healthy parent suggesting either this duplication is unrelated to the phenotype or this mutated allele in not fully penetrant. To further elucidate the involvement of MBD5 in ID, we sequenced coding and non-coding exons in a selected cohort of 78 subjects with a phenotype reminiscent of 2q23.1 microdeletion syndrome. We identified for the first time a de novo nonsense mutation associated with a much more damaging phenotype without walking and verbal speech at the age of 10 years. Besides this fully penetrant mutation, we identified four missense variants most often inherited from a healthy parent. One of these, the p.Gly79Glu variant, has been recently described as an allele risk for autism spectrum disorders. Taken together, our findings suggest MBD5 gene is sensitive to perturbation by multiple mutational mechanisms, leading to variable phenotypic outcomes.

To date, the complexity of genetic causes of Intellectual Disability (ID) makes difficult the molecular diagnostic of patients who do not present with clinical features evoking a specific syndrome. We report here the case of a severely affected young boy for whom molecular, cytogenetic and biochemical investigations had failed to identify the etiology of its ID. During the targeted high-throughput resequencing of 220 ID genes, a complex anomaly was detected in exon 4 of *MECP2* gene in this patient. This mutation is a deletion of 139bp of exon 4 additioned by two inverted insertions of intron 2 sequences, which leads to the replacement of 41 amino acids but keeps the reading frame downstream of the rearrangement. This mutation was inherited from the mother who presents with mild cognitive impairment, but no Rett syndrome phenotype despite an unbiased X-inactivation in blood. We review and discuss all the other *MECP2* rearrangements and mutations reported in males in literature and the associated clinical phenotypes.

Impact of the overexpression and deficiency of Mecp2 in mice: a balance always to maintain.

R. El Khoury, N. Panayotis, A. Ghata, V. Matagne, G. Alcaraz, L. Villard, ***J. ROUX****;
UMR_S910, Marseille, France.*

The X-linked methyl-CpG binding protein 2 gene (Mecp2) plays a role in the regulation of chromatin architecture, gene expression and fine tune of adult neurons. An abnormal dosage of this protein causes a large group of neurological disorders. Mutations or deletions in MeCP2 gene cause Rett syndrome in females, whereas its overexpression causes the Mecp2 duplication syndrome in boys. A fine control of the amount of MeCP2 protein is necessary for a normal function of neurons. Several mouse models were generated to mimic the Mecp2-pathies. Here, we studied mice with a double expression of Mecp2 (Mecp2Tg1) (Collins et al, 2004) to get closer to the human case of duplication. We used a battery of behavioral tests: grip strength, rotarod, open field and the respiratory profile of the Mecp2Tg1 mice during postnatal development. In parallel, in vivo studies were made in different parts of the nervous system, on a set of transcripts regulated by Mecp2. Our results show that Mecp2Tg1 mice exhibit behavioral disorders: At 5 weeks, these mice appear hyperactive and anxious. Much later (from 35 weeks), they develop spasticity and seizures. This is followed by a period of hypoactivity and kyphosis. The clinical implications of our study are twofold: first we seek to understand the phenotypic effects of a double dose of Mecp2. Second, gene therapy projects are being evaluated on MeCP2-deficient mice. Since the level of MeCP2 must be tightly regulated, a good control of Mecp2 dosage will be necessary in order to prevent overdosage of the protein.

P05.101
GABA and Glutamate metabolisms are affected in the brain of Mecp2-deficient mouse.

R. El Khoury, N. Panayotis, A. Ghata, V. Matagne, G. Alcaraz, L. Villard, ***J. ROUX****;
INSERM UMR_S910, Marseille, France.*

Rett syndrome (RTT) is a severe neurological disorder that affects female patients. RTT is caused by mutations in the X-linked methyl-CpG binding protein 2 (MECP2) with an incidence of 1/15000. RTT patients develop normally until 6-18 months of age, before the onset of deficits in autonomic, cognitive, motor functions (stereotypic hand movements, impaired locomotion) and autistic features. Studies on Mecp2 mouse models revealed a severe deregulation in the neurotransmission. In particular, bioamine de-

ficits have been primarily and extensively studied in Mecp2 deficient mice. Dysfunction of the gabaergic and glutamatergic systems has been also pointed out since the balance between brain excitation and inhibition appears affected in the brain of the Mecp2 deficient mouse. However, the results are divergent due to the differences in the age and tissues studied. To date few projects have been dedicated to the follow GABA and Glutamate metabolism in eight different brain areas of the Mecp2-deficient mice. In the present study we used real-time PCR, western blotting and HPLC to compare the GABA and Glutamate metabolism in several key areas of the Mecp2 mutant mice brain at different developmental stages (early and late symptomatic). Key enzymes (Kcc2, Nkcc1, Vglut1/2, Gad1/2) will be considered. In conclusion, our results revealed a spatial and temporal deregulation of the glutamatergic and gabaergic systems for all levels of regulations studied. Moreover, we found that pharmacological stimulation of the gabaergic system is efficient to improve the lifespan of Mecp2 deficient mice.

Duplication of Xq28 including the *MECP2* gene has been primarily described in male patients with severe developmental delay, constipation, epilepsy, hand stereotypies and recurrent infections. In the first part of this work, we carried out an epidemiological study that permitted to identify 95 patients in France carrying a *MECP2* duplication of less than 4 Mb (86 males and 9 females ranging from 0 to 40 years) since the implementation of MLPA and array-CGH. 84 patients carried a pure interstitial duplication of various size and 11 patients a complex rearrangement. In the second part of the study, we report on the clinical manifestations of 45 patients of the series. 27 patients were examined by the same physician and a standardised form was sent in the remaining 18 patients. Besides to the classical clinical features, we describe frequent manifestations insufficiently reported in the literature including tapering fingers, flessum attitude due to progressive spasticity and translucent skin with prominent veins. 77% of patients had brain abnormalities consisting mainly in corpus callosum malformations and ventricular dilatation. We particularly focus on the affected females phenotype that can be similar to that observed in males, especially when the *MECP2* duplication results from an unbalanced X-autosome translocation. Careful genetic counselling should be given to couples at risk, given the risk of abnormal phenotype in females. The third part of the study consisting in searching genotype-phenotype correlations is in progress, in order to check if the different sizes of the duplication can be associated to variable clinical features.

Cytogenetic Microarray for Delineation of Cryptic Genomic Rearrangements in Mental Retardation

S. Agarwal[1], *S. Muthuswamy*[1], *I. Panigrahi*[2];
[1]*Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India,* [2]*Post Graduate Institute of Medical Sciences, Chandigarh, India.*

Mental retardation (MR) is a variable, heterogeneous manifestation of central nervous system dysfunction, present in 1-3% of general population. Many environmental and genetic factors can cause MR, including premature birth, prenatal infections, chromosomal abnormalities, and single-gene mutations. Though an etiology can be established in 60-75% of cases of severe MR, it is only 38-55% in mild cases. Moreover, genetically determined MR accounts by for 17 to 41% of cases, depending on use of the different techniques. In the present study, we report the cryptic genomic rearrangements identified MR cases by selective use of chromosomal microarray.
Methodology: Two cases of unexplained MR after initial biochemical, radiological and chromosomal evaluation were studied. DNA was extracted from whole blood and analysed on Illumina HumanCytoSNP-12 array. Raw data obtained was analysed with KaryoStudio software. The rearrangements were checked in DECIPHER database.
Results and Conclusion: Both the samples showed a male karyotype and some cryptic genomic rearrangements. First case had multiple rearrangements-duplications in the chromosome 7q11.21 (398kb) and 17q12 (186kb), and 1.6Mb hemizygous deletion at cytoband 14q13.3-q21.1. Second case was observed to have a duplication of 549Kb at 7q36.2, region associated with autism spectrum disorder and amyotrophic lateral sclerosis; a 2.6Mb hemizygous deletion at 22q11.21 q11.22 region. All these regions (non-recurrent genomic aberrations) have been implicated as pathogenic in several other patients as per DECIPHER database. Thus, chromosomal microarray analysis can help in identifying underlying cause of MR in some apparently unexplained cases, and should be a diagnostic tool for evaluation of MR.

Plasma levels of leptin and adiponectin in Fragile X syndrome

M. Z. Lisik[1], *A. Pyrkosz*[1], *E. Gutmajster*[1], *J. E. Zejda*[2], *M. Olszanecka-Glinianowicz*[3], *A. L. Sieron*[1];
[1]*Department of General, Molecular Biology and Genetics, Katowice, Poland,* [2]*Department of Epidemiology Medical University of Silesia, ul. Medyków 18,, Katowice, Poland,* [3]*Department of Pathophysiology Medical University of Silesia, ul. Medyków 18,, Katowice, Poland.*

Fragile X syndrome (FXS) is the most common form of familial mental retardation and one of the leading known causes of autism. The mutation responsible for FXS is a large expansion of the CGG repeats in the promoter region of the *FMR1* gene resulting in its transcriptional silencing. Leptin may be considered a cytokine-like hormone with pleiotropic actions since it may be involved in the regulation of neuroendocrine functions, immune system, in addition to its role in development. Leptin and adiponectin may act in parallel as opposing metabolic counterparts. Thus, we hypothesized on involvement of adiponectin in the pathophysiology of autism.
Material and methods
23 male patients, mean age 19,3 ± 6,6, affected by Fragile X syndrome (full mutation in the *FMR1* gene), were enrolled into the study. Controls were 24 healthy males, mean age 21,8 ± 5,8. Plasma leptin and adiponectin levels were determined by ELISA method.
Results
Plasma leptin levels in Fragile X syndrome patients were similar as in control group (11,53 ± 10,24 ng/ml) vs (5,73 ± 4,52) were not significantly different from those found in controls (p = 0,5).
While plasma adiponectin levels in Fragile X syndrome patients (6,68 ± 3,44 ng/ml) were significantly lower in controls (8,95 ± 4,24) (p< 0,04).
Conclusion
Adiponectin may be involved in autistic features observed in FXS patients in light of its anti-inflammatory properties. Further investigations are necessary to evaluate the role of adipokines in FXS.

P05.105

Clinical utility of the chromosomal microarray analysis in patients with neurodevelopmental disorders.

M. Rosello, *F. Martinez, S. Mayo, S. Monfort, S. Oltra, C. Orellana;*
Hospital Universitario y Politecnico „La Fe", Valencia, Spain.

Developmental delay/intellectual disability (DD/ID) affects 1-3% of the population. The study of the DD/ID is one of the most complex fields of human genetics because of their high clinical and genetic heterogeneity. In the last decade, the application of genome analysis technologies to the study of chromosomes has enabled dramatic progress in the field of clinical genetics.
The objective of this work is the study of these anomalies, which not only helps to determine the genetic causes of these disorders, but also allows to correlate genotype-phenotype and to define the clinical and behavioral characteristics of these microduplication and microdeletion syndromes. An accurate diagnosis is the key providing genetic counseling that helps the family to take reproductive decisions.
We have applied array-CGH (44,000 60 mer probes and/or 6,000 BAC clones) in a cohort of 246 patients with DD/ID, congenital anomalies (CA), facial dysmorphysm and/or positive family history for ID, CA or miscarriages. We have collected 109 different clinical variables for each patient.
We have found a pathogenic or potentially pathogenic chromosomal imbalance (pCNVs) in 29.7% of patients. Comparison of the clinical data showed that hands and/or feet abnormalities were the most frequent congenital anomaly (55%) and was statistically more frequent in children with pCNVs (63%; p-value 0.05). Further clinical criteria indicate a higher probability of a chromosomal aberration causative for DD/ID was skeletal defects, microcephaly, genital abnormalities and congenital heart defects.
Our results reinforce the importance of clinical criteria in the application of array-CGH in patients with neurodevelopmental disorders.

Searching for microcephaly genes amongst an endogamous population

S. A. Lynch[1], *H. Murphy*[2], *S. Ennis*[3], *J. P. Casey*[4];
[1]*National Centre for Medical Genetics, Dublin, Ireland,* [2]*Dept of Genetic Medicine, Manchester, United Kingdom,* [3]*School of Medicine and Medical Science UCD, Dublin, Ireland,* [4]*National Children's Research Centre, Dublin, Ireland.*

Irish Travellers are an endogamous population numbering 26,000 in the Irish Republic. First cousin marriage is common and they operate a clan within a clan structure. This project focuses on two clans with microcephaly (<3SD) and normal MRI scans. Microcephaly is common and proving it is homogeneous is difficult clinically. The first family (A) consist of 3 affected children. One child is more severely disabled than his siblings raising the possibility of sibship heterogeneity. The second family (B) consist one affected child and 4 affected maternal grandaunts with a similar microcephaly phenotype.
SNP homozygosity mapping showed that the affected individuals from both families share 12 and 6 regions of homozygosity (ROH) respectively.
Comparison of the homozygosity patterns across the families identified a single shared ROH (5.6 Mb) on chromosome 11. However, exome sequencing did not identify a shared recessive mutation within the candidate locus, suggesting that (i) the two families may have different disease genes or (ii) the shared disease mutation is regulatory/non-coding. One affected from each clan share mutations in a candidate gene, but these mutations are not found in other affecteds from either family.
Exomic sequencing unexpectedly revealed that 1 affected individual each from family A and B had McArdles disease confirming that they are from the same wider clan. Neither had signs of this disease.
Our analytic approach has been to accommodate heterogeneity both between and within families. This study highlights the complexities of this analysis & the unexpected identification of disease genes through exomic sequencing.

Many novel candidate genes for intellectual disability (ID) have been identified in microdeletions. However, our etiological understanding of these genes often remains unclear. So far, only targeted expression experiments provided evidence e.g. for functional interactions between novel and well-established ID genes or for the haploinsufficiency of deleted candidate genes. However, genome-wide and hypothesis-free expression analyses have not yet been applied to non-recurrent microdeletion syndromes to systematically study functional interactions and pathways.
We performed genome-wide expression studies on 14 patients with non-recurrent 5q14.3-q15 microdeletions using Illumina HT12 expression arrays and whole blood RNA. Adapting an established analysis protocol, we first compared all transcripts with reliably detectable signals (detection p-value / DPV<0.01) between patients and controls and demonstrated significantly reduced TRABD expression in patients (verified by qPCR). However, this protocol may exclude those transcripts with the largest expression difference between patients and controls. Thus, we developed a novel strategy to identify transcripts that met the above-mentioned DPV threshold EITHER in controls OR in patients. We identified several additional genes. Due to limited RNA, only one of these, COX7B, was verified by qPCR. Both the significant correlation of the transcript levels of TRABD / COX7B with MEF2C, the recently identified causative gene in 5q14.3 microdeletion syndrome, and the fact that TRABD and COX7B were connected to MEF2C over only two „nodes" in a network analysis pointed to a biological significance of the interactions.
Thus, both analysis protocols yielded verifiable and biologically significant results, demonstrating the applicability of genome-wide expression studies to non-recurrent microdeletions.

An emerging phenotype of microdeletion Xq22 involving *PLP1* gene in females. Case reports of four independent patients

M. Stefanova[1], *A. Wilsdon*[2], *S. Joss*[3], *A. Erlandsson*[1], *K. Shimojima*[4], *M. Suri*[2], *S. Shimada*[4], *N. Sangu*[4], *L. Samuelsson*[1], *T. Yamamoto*[4];
[1]*Sahlgrenska University Hospital, Gothenburg, Sweden,* [2]*Nottingham City Hospital, Nottingham, United Kingdom,* [3]*Southern General Hospital, Glasgow, United Kingdom,* [4]*Institute for Integrated Medical Sciences, Tokyo, Japan.*

Pelizaeus-Merzbacher Disease commonly results from duplications of the PLP1 gene at Xq22, with males being affected and females usually healthy carriers. Microdeletions encompassing PLP1 in females with severe intellectual disability have not been described previously. Here we present four females with deletions at Xq22.1-q22.3 involving PLP1.
The four patients of British, South Asian, Swedish and Japanese origin are aged 19, 8, 7 and 3 years respectively. All presented with severe intellectual disability and cerebral abnormalities including generalized white matter and corpus callosum hypoplasia, atrophy and delayed myelination. The two eldest patients walked independently from 6 and 7 years, but have no speech

and impaired comprehension. Additional features seen in one or more cases include: polyhydramnios, distinct sleeping disturbances, purposeless hand movements, mutilation, hearing loss, overgrowth/delayed growth, slow growing hair and deep palmar creases. Neurological features include severe hypotonia, seizures and cortical blindness. Skeletal features include advanced bone age, proximal placed thumbs, severe pes equinovarus, extremely short feet and overriding toes. No patient showed developmental regression or periventricular leucomalacia. There is no distinctive dysmorphology.
Array analysis detected de novo Xq22 deletions 3Mb, 85kb, 4.5Mb and 4.9Mb in size, all encompassing PLP1. X-inactivation studies in blood were unquantifiable but skewed in two, 79:21 skewed and non-informative respectively. Clinical and molecular features of all four females with Xq22 deletions suggest a new microdeletion syndrome separate from Pelizaeus-Merzbacher disease. The smallest deletion contains only PLP1, along with transmembrane protein 31 (TMEM31) and glycine receptor, alpha 4 (GLRA4) about which we have very limited information.

Intellectual disability (ID) is characterized by an extraordinary genetic heterogeneity, with more than 200 genes implicated in monogenic forms. This complexity precluded systematic testing for mutations and because clinical features are often non-specific, for some of these genes only few cases or families have been unambiguously documented. It is the case of the the X-linked gene encoding monoamine oxidase A (MAOA), for which only one nonsense mutation has been identified in Brunner syndrome, characterized in one unique family by borderline ID and impulsive and aggressive behaviors. We have developed targeted NGS sequencing of 220 ID-genes in patients with undiagnosed ID. We identified a p.C266F missense mutation in MAOA in a boy with autistic features and behavioral disturbances. He has good verbal comprehension but IQ could not be measured due to attention deficit and heterogeneous results in WISC-IV test. Two maternal uncles carry the mutation and have severe ID, with a history of maltreatment in early childhood. The phenotype overlaps with Brunner syndrome. This novel missense mutation decreases MAOA activity, as shown by abnormal levels of urinary monoamines and by measurement of enzymatic activity. The identification of this point mutation confirms, for the first time since 1993, the monogenic implication of the MAOA gene in ID, autistic features and behavioral abnormalities. Variable expressivity might be due to environmental factors. We will discuss possible therapeutic options and hypotheses that could account for the very long time lag between the initial and highly publicized report and the finding of a second family.

P05.110

Microduplication disrupting the *MYT1L* gene in a familial case of intellectual disability, and neuropsychiatric disorder.

M. Willems[1], *A. Schneider*[2], *M. Girard*[2], *M. Tournaire*[2], *N. Ruiz-Palares*[2], *M. Barat*[3], *I. Touitou*[3], *B. Echenne*[4], *G. Lefort*[2], *D. Geneviève*[1], *L. Pinson*[1], *J. Puechberty*[1];
[1]*Département de Génétique Médicale, Hôpital Arnaud de Villeneuve, Montpellier, France,* [2]*Département de Cytogénétique, Hôpital Arnaud de Villeneuve, Montpellier, France,* [3]*Laboratoire de Biologie Moléculaire, Hôpital Arnaud de Villeneuve, Montpellier, France,* [4]*Département de Neuropédiatrie, Hôpital Gui de Chauliac, Montpellier, France.*

MYT1L is a member of the myelin transcription factor 1 gene family and is highly expressed in mouse embryonic brain. MYT1L interacts directly with DISC1, which is involved in schizophrenia. We describe a family in which the father, his son and his daughter have a 549 kb interstitial duplication in the 2p25.3 region detected by array comparative genomic hybridization and confirmed by quantitative PCR. This duplication encompasses the five first exons and is predicted to disrupt the *MYT1L* gene. The phenotype includes: slight facial features including bulbous nasal tip, wide mouth, overfolded helix, strabismus, moderate intellectual disability (ID) with speech impediment, hypotonia, hyperactivity, mood disorder with aggressive behaviour, neonatal feeding difficulties followed by a tendency to hyperphagia with overweight and a prominent abdomen with thick panniculus adiposus. Partial deletions of chromosome band 2p25.3 encompassing the *MYT1L* gene have been reported in patients presenting with ID and overweight whereas duplications disrupting the *MYT1L* gene have been reported in patients presenting with autism and schizophrenia. Moreover, single-nucleotide polymorphisms (SNPs) of *MYT1L* contribute to major depressive disorder and schizophrenia. Recently, de Ligt et al. reported a „de novo" splice site mutation of the *MYT1L* gene identified by exome sequencing in a patient with severe ID, autistic features, neonatal hypotonia and feeding difficulties, as well as mild facial features.
This report and previous publications strongly suggest that alterations of the *MYT1L* gene are responsible for diverse neuropsychiatric disorders with intellectual disability and a tendency to overweight.

Structural variations are common genetic hallmarks in patients with developmental delay or congenital malformations. Although SVs are present in relatively healthy individuals (10^{-4} mutation rate) and have been annotated comprehensively in 1000 Genome Project, however, when arise *de novo* in the germline, it has been shown to be an informative path towards identifying causative mutations in human diseases. We apply genome-wide paired end tag sequencing in 8 patients carrying *de novo* or familial segregating chromosomal aberrations with intellectual disability (ID). For one *de novo* patient, we included the parents for genome sequencing investigation, and applied variants filtering to exclude parental SVs. The ratio of paternal and maternal inheritance rate is relatively balanced (52% : 46 %) and after applying variants filtering, we obtained four *de novo* SVs, in which 2 SVs are balanced translocation disrupting *GTDC1* gene at chromosome 2 and two other SVs did not coincide within a coding region/TF-binding sites from recent ENCODE release dataset. The transcript level of all *GTDC1* isoforms is reduced in the patient's lymphoblasts compared to the control. The expression profile of *GTDC1* is ubiquitous across different tissues, including the brain. We further investigated the loss of function effect of *GTDC1* in neural precursor cells and neurons derived from mouse embryonic stem cells, and found reduced number of neurons in the *GTDC1* depleted cells. This implicates *GTDC1* as an eligible candidate for ID and screening validation in larger cohort of patients is required to provide a stronger evidence for its involvement in ID.

P05.112

Two brothers with mental retardation and microduplication Xp22.32-p22.31

M. Pizzino, *S. Meduri, C. Pidone, I. Loddo, E. Germanò, A. Gagliano, S. Briuglia;*
Genetics and Pediatric Immunology, Messina, Italy.

Neuroligins (NL) are synaptic cell adhesion molecules that bind specifically

to a set of synaptic membrane proteins called neurexins. In humans, this protein family is encoded by five genes, NLGN1, -2, -3, -4 and -4Y. Several recent studies have implicated NL in autistic disorders and mental retardation. The functional role predicts that mutations and/or polymorphisms in NLGN genes may be implicated in the development of neuropsychiatric disorders.
We describe two brothers born to non-consanguineous parents, with a family history of mental retardation (elder brother 16 years-old). Both had showed delayed psychomotor development and language disorders; phenotypic examination were negative except for long and asymmetric face; clinodactyly of the 5th finger of hands were present only in the second brother. Brain MRI were normal. The karyotype analysis and genetic analysis for X-fragile syndrome were negative. Both have performed array-CGH which showed a microduplication Xp22.32-p22.31 (5,842,988-6,106,308)x2 mat. The mother was heterozygous unaffected. Our observation helps to confirm the pathogenic role of this microriarrangements. The microduplication highlighted our patients is in the short arm of the X chromosome that includes NLGN4 gene. Our cases and the data in literature suggest that neurodevelopmental defects in autism spectrum disorders and mental retardation (MR) could be related to a reduced function of this protein.

P05.113
Alteration in synaptic genes *NRXN1* and *NLGN4* may predispose to neurological syndromes

V. Becvarova[1], *L. Hnykova*[1], *H. Machkova*[1], *E. Hlavova*[1], *G. Kreckova*[1], *J. Horacek*[1], *I. Soldatova*[1], *M. Putzova*[1], *D. Stejskal*[1], *M. Godava*[2], *E. Zemankova*[3], *M. Trkova*[1];
[1]*GENNET, Prague, Czech Republic,* [2]*Department of medical genetics, University Hospital, Olomouc, Czech Republic,* [3]*E-med, Benesov, Czech Republic.*

Neurexins and neuroligins are proteins functionally connected by interaction in synaptic network formation and maitenance. According to recent studies alteration in *NRXN1* (2p16.3) and *NLGN4* (Xp22.3) genes can predispose to the wide spectrum of neurodevelopmental disorders including autistic spectrum disorders, intellectual disability, speech and language delay, hypotonia and schizophrenia. *NRXN1* as one of the largest known human genes (1,1 Mb) tends to frequent intragenic alterations. Whole genome genotyping was performed using the Illumina HumanCytoSNP 12v2.1.
We present 3 children of comparable age (5-6 year old), having different size of microdeletion in isoform alpha1 *NRXN1* gene (40 - 360 kb) and slightly different phenotype. All children had mild to moderate mental retardation, two of them had speech delay and anxiosity, hypotonia and facial dysmorphism. Two of detected deletions were intronic, the third deletion covered exones 1 to 11 of *NRXN1*. As the deletion in the *NRXN1* may not be fully penetrant, we examine also parental DNA.
Microduplication (300 kb) spanning the exones 1,2 and 3 of *NLGN4* gene was found in 22 year old patient with hyperkinetic syndrome, attention failure, but without mental retardation. The same duplication was detected in clinically normal mother and maternal cousin with Asperger syndrome. Thanks to this family examination prenatal array diagnosis in a new pregnancy could be provided. Consequently proband´s brother without duplication in *NLGN4* was born.

P05.114
Genotype-phenotype correlations of *NRXN1* deletions

C. Dubourg[1,2], *H. Hamdi*[1], *L. Pasquier*[3], *A. Fievet*[1], *C. Quélin*[3], *S. Jaillard*[4], *H. Journel*[5], *M. Beaumont-Epinette*[1], *J. Mosser*[6,2,7], *S. Odent*[3,2], *V. David*[1,2];
[1]*Laboratoire de Génétique Moléculaire, CHU, Rennes, France,* [2]*UMR 6290 CNRS, IGDR, Rennes, France,* [3]*Service de Génétique Clinique, CHU, Rennes, France,* [4]*Laboratoire de Cytogénétique, CHU, Rennes, France,* [5]*Service de Génétique Médicale, CHBA, Vannes, France,* [6]*Laboratoire de Génomique, CHU, Rennes, France,* [7]*Plateforme Biogenouest Génomique Santé, Rennes, France.*

Chromosomal microarray is now a key diagnostic test for patients with developmental disabilities. This analysis led us to the identification of intragenic deletions of the *NRXN1* (neurexin 1) gene, in eight unrelated patients with intellectual disability (8/8), speech delay (8/8), autism spectrum disorders (5/8) and epilepsy (2/8). The size of these deletions varies from 50 to 600 kb.
The *NRXN1* gene encodes a protein that belongs to a family of cell adhesion molecules and plays a fundamental role in synaptic function. *NRXN1* transcription results in two isoforms α and β. The α neurexins are transcribed from a promoter located upstream of exon 1, while the β neurexins are transcribed from an intragenic downstream promoter.
The main majority of our deletions (7/8) alter the α isoform only, and five of them involve exonic sequences whereas three deleted intronic regions only. One case occurred *de novo*. Two cases are familial ones and the exonic deletion is inherited from one parent who presented learning difficulties. The five other cases are inherited from an asymptomatic parent or do not segregate with the phenotype in the siblings, even if the deletion involves exonic regions.
This heterogeneity of genotype-phenotype correlations of intragenic *NRXN1* deletions implies that the greatest care must be taken in the cytogenetic report, and that deletions of this gene may participate in the phenotype but are probably not sufficient to give rise to the neurodevelopmental disorder.

P05.115
More or Less: reverse phenotypes as a consequence of reciprocal 5q35 deletions and duplications

O. Zilina[1,2], *R. Mägi*[3], *A. Kurg*[1], *K. Õunap*[2,4];
[1]*Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia,* [2]*Department of Genetics, United Laboratories, Tartu University Hospital, Tartu, Estonia,* [3]*Estonian Genome Center, University of Tartu, Tartu, Estonia,* [4]*Department of Pediatrics, University of Tartu, Tartu, Estonia.*

The recent implementation of array techniques in research and clinical practice has revealed the existence of recurrent reciprocal deletions and duplications in several genome loci. The most intriguing feature is that some reciprocal genomic events can result in opposite phenotypic outcome. One of such examples is 5q35.2-q35.3. Deletions in this locus, encompassing NSD1 gene, lead to Sotos syndrome (Sos) characterized by childhood overgrowth with advanced bone age, craniofacial dysmorphic features including macrocephaly, and learning difficulties; while duplications have been proposed to manifest in opposite phenotype related to growth. Short stature since the birth, microcephaly, brachydactyly, delayed bone age, mild to moderate intellectual disability and mild facial dysmorphism seem to be characteristic features of 5q35.2-q35.3 duplication. It has been proposed that NSD1 plays a role in regulation of somatic growth in humans. Obviously, gene expression studies might be the first step towards the understanding the exact mechanisms of the influence of 5q35.2-q35.3 structural changes in general and NSD1 particularly on human growth.
We aimed to figure out the gene expression pattern differences in patients with 5q35.2-q35.3 deletion and duplication. The expression of 16 genes from Sos critical region and flanking regions was studied by RT-qPCR. Most of the genes showed correlation between their copy number and expression level. In addition, whole-genome expression was analyzed using HumanHT-12 v4 Expression BeadChip (Illumina Inc.) to estimate the global influence of these chromosomal aberrations. Although, some expected changes were observed, more patients are needed to make any statistically significant conclusions.

P05.116
Molecular diagnosis of deletions and duplications associated with syndromic obesity

C. S. D'Angelo, *C. P. Koiffmann;*
Institute of Biosciences, University of Sao Paulo, Sao Paulo, Brazil.

Some rare genetic syndromes lead to obesity, often associated with intellectual disability, abnormal development, dysmorphic features and congenital malformations. Prader-Willi syndrome (PWS) is the most common syndromic form of obesity, caused more specially by deletions in the paternally derived 15q11q13 region. Other genomic disorders associated with copy number variants (CNVs), such as chromosomal deletions of 1p36, 2q37, 6q16, 9q34, 11p13 and 17p11.2, have an increased prevalence of obesity. Moreover, an increasing number of CNVs linked to obesity are being identified in recent years. Nearly 300 patients with syndromic obesity were evaluated for chromosomal imbalances by MLPA after DNA methylation analysis ruled out PWS. Half of these patients were further investigated with different array platforms. Among the pathogenic CNVs, we identified syndromic genomic disorders, such as deletions of 1p36 (7 cases), 2q37 (HDAC4; 5 cases), 6q16 (SIM1; 2 cases), 9p24 (3 cases), 9q34 (EHMT1; 1 case), and 17p11.2 (RAI1; 5 cases), as well as specific CNVs already linked to obesity, such as 1p21.3

and 2p25.3 deletions. Additionally, we identified 22q11.2 deletion causing DiGeorge syndrome (6 cases), 22q11.2 duplication syndrome (1 case), and 22q11.2 distal deletion syndrome (2 cases). Known genomic disorders with incomplete penetrance and variable expressivity included 15q11.2 deletion of NIPA1 (2 cases), 16p11.2 deletion of SH2B1 (1 case), 16p11.2 duplication of TBX6 (1 case), 16p13 deletion of MYH11 (1 case), 17q11.2 duplication of NF1 (1 case), and 17q21.31 duplication of MAPT (1 case). Clinical variability in well-known syndromes may facilitate the identification of disease genes.

Pallister-Killian syndrome: an under-diagnosed syndrome?

P. Letard[1], *C. Dupont*[1], *Y. Capri*[2], *C. Baumann*[2], *S. Drunat*[3], *M. Montagnon*[1], *A. Verloes*[2], *B. Benzacken*[4,5], *A. C. Tabet*[1];
[1]*Cytogenetic Department, AP-HP, Robert Debré University Hospital, Paris, France,* [2]*Medical Genetic Department, AP-HP, Robert Debré University Hospital, Paris, France,* [3]*Molecular Genetic Department, AP-HP, Robert Debré University Hospital, Paris, France,* [4]*Cytogenetic Department, AP-HP, Jean Verdier University Hospital, Bondy, France,* [5]*University of Paris North Paris XIII, Bobigny, France.*

Pallister-Killian syndrome (PKS) is usually described as a rare syndrome caused by the presence of a supernumerary mosaic isochromosome 12p (i(12p)) in patients presented with multiple congenital anomalies, characteristic dysmorphic features, pigmentary skin anomalies, seizures and severe developmental delay. The gold standard diagnostic requires skin biopsy establishing the karyotype in normal and abnormal pigmented skin. Nevertheless, PKS can be associated with mild or unusual phenotype making the diagnosis and the genetic counselling difficult.
Here we report two cases; the first one is a 1-year-old patient with severe developmental delay, atypical facial features, cardiac malformation, hirustism and ulnar drift. Chromosome analysis on peripheral lymphocytes showed a normal karyotype. The PKS diagnosis was suspected because the assessment of subtelomeric rearrangements by MLPA technique showed a trisomy 12pter. The PKS was confirmed by FISH using D12Z1 probe on jugal and peripheral blood smears. The second case is a patient with prenatal diagnosis of tetrasomy 12p. Despite a reserved counselling, a boy was born at term. At 5 years old, he presented with minor pigmentary skin anomalies, no dysmorphic features and very mild developmental delay.
The first case highlights the difficulty of the diagnosis in absence of typical phenotype. It also confirms that the diagnosis can be performed by buccal and/or peripherical blood smears using FISH techniques without skin biopsy. The second observation highlights the variability of the phenotype leading to a difficult prenatal genetic counselling. Together, these observations suggest that PKS is a probably under-diagnosed syndrome.

P05.118
Partial deletion of TCF4 in two sisters of whom only one had typical Pitt-Hopkins syndrome

A. S. Plomp[1,2], *R. C. M. Hennekam*[1], *J. Kleyer*[3], *L. C. Knegt*[1], *A. M. Polstra*[1];
[1]*Academic Medical Center, Amsterdam, Netherlands,* [2]*Netherlands Institute for Neuroscience, Amsterdam, Netherlands,* [3]*Medische Dienst Talant, Drachten, Netherlands.*

Haploinsufficiency of the TCF4 gene is known to cause Pitt-Hopkins syndrome, characterized by severe intellectual disability, epilepsy, hyperventilation, microcephaly and facial dysmorphism.
The proband is a 23-year-old female with psychomotor retardation since birth. She walked without support at the age of three years and has never had any meaningful speech. She walked somewhat ataxic with flexed elbows. She has brachycephaly, a broad nose, a large mouth with full, everted lips, laxity of finger joints and flat feet. Her nine years younger sister also has intellectual disability. She walked independently at the age of two years. Speech development was retarded, but eventually she learned to speak well. She visited a normal primary school for two years followed by special education. She can read and write a little and plays computer games. She has obesity (BMI=32), mildly upslanting palpebral fissures, otherwise no dysmorphism.
Array CGH analysis (Agilent 180K oligo-array; AMADID 023363) revealed an interstitial deletion of 67 kb at chromosome band 18q21.2 comprising part of the TCF4 gene in both sisters. Array CGH analysis and FISH examination in the phenotypically normal father showed the same deletion in about one third of his lymphocytes.
In conclusion, the same partial deletion of TCF4 can cause typical Pitt-Hopkins syndrome and aspecific intellectual disability, respectively, in two sisters. Apparently, the phenotype of TCF4 disruption is broader than previously thought. As far as we know, this is the second report of recurrence in sibs and somatic mosaicism in the parent, which is important for genetic counseling.

Three novel WDR62 mutations in a consanguineous Turkish family and in a non-cansanguineous European patient: further molecular investigations and clinical manifestations

S. Moortgat[1], *I. Maystadt*[1], *M. Abramowicz*[2], *J. Parma*[2], *J. Désir*[1];
[1]*Centre de Génétique Humaine, Institut de Pathologie et de Génétique, Charleroi (Gosselies), Belgium,* [2]*Centre de Génétique Humaine, Hôpital Erasme-ULB, Brussels, Belgium.*

Autosomal recessive primary microcephaly (MCPH) is a genetic disorder of brain growth characterized by small brain, variable degree of mental retardation and occasionally mild seizures. It is genetically heterogeneous with nine genes involved so far.
WDR62, coding for a centrosomal protein, is the second most commonly implicated gene, preceded by *ASPM.* Cortical malformations, not described in classical MCPH phenotype, are often present in *WDR62* mutated patients. We report on 2 families with three novel mutations in *WDR62*. The first proband is the only child of a non-consanguineous European couple. She presents with mild microcephaly (-2.5SD), developmental delay, moderate mental retardation and epilepsy. Cerebral MRI shows mild pachygyria and simplified cerebral cortex. Sanger sequencing of *WDR62* identified compound heterozygous mutations: a nonsense mutation c.2788C>T resulting in a premature stop codon (p.Gln930X) and a synonymous variant c.1521G>A (p.Leu507Leu). Functional studies were performed on cDNA and an aberrant splicing of exon 11 confirms the pathogenicity of this unknown variant. Both parents are healthy heterozygous carriers of one of the mutations.
The second proband, third child of consanguineous Turkish parents, presents with moderate microcephaly (-4SD) and mental retardation. Cerebral MRI does not reveal any brain malformation, except microcephaly. Sequencing identified a homozygous missense mutation c.1526C>T (p.Ser509Leu) in *WDR62.*
These three mutations have not been reported before. We discuss the molecular results, the phenotypic heterogeneity and the prevalence of this gene in MCPH patients from variable ethnicity, even in non-consanguineous populations, and in patients with mild phenotype and no obvious cortical malformations.

Rett syndrome (RTT) is a monogenic disorder manifesting as a large variety of phenotypes ranging from very severe to mild disease. Since there is a weak correlation between the mutation type in the Xq28 disease gene MECP2/X-inactivation status and phenotypic variability, we used this disease as a model to unveil the complex nature of a monogenic disorder. Exome sequencing was used to analyze the functional portion of the genome of two pairs of sisters with RTT. Although each pair had the same MECP2 mutation and balanced X-inactivation, one individual from each pair could not speak or walk, and had a profound ID (classical RTT), while the other could speak and walk, and had a moderate ID (Zappella variant). In addition to the MECP2 mutation, each patient has a group of variants predicted to impair protein function. The classical RTT girls, but not their milder affected sisters, have an enrichment of variants in genes related to oxidative stress, muscle impairment and ID and/or autism. On the other hand, a subgroup

of variants related to immune system modulation, exclusive to the Zappella variant are driving toward a milder phenotype. Togheter our results indicate that the final phenotype is likely the result of a combination of MECP2 mutation, X-inactivation and around 40 disrupting variants in other genes. We demonstrate that exome analysis has the potential to provide insights into disease pathophysiology. Most importantly, hereby identified genetic modifiers of speaking, walking and intellectual capabilities may represent targets for new therapies (accepted by PLOS ONE).

Bio-distribution and efficacy of a self-complementary AAV9 construct expressing a codon-optimized Mecp2 transgene for further use in a preclinical model of Rett Syndrome

V. Matagne[1], *M. Barkats*[2], *L. Villard*[1], *J. Roux*[1];
[1]*INSERM U910 / Université Aix-Marseille, Marseille, France,* [2]*Institut de Myologie, Université Pierre et Marie Curie, Paris, France.*

Rett syndrome (RTT) is an X-linked neurodevelopmental disorder primarily affecting CNS functions but also peripheral functions. There is currently no cure for the disease and treatments available are aimed at improving RTT symptoms. Most RTT cases are due to mutation in methyl CpG binding protein 2 (MECP2), whose main function is that of a global transcriptional repressor.
The recent findings that reactivation of Mecp2 rescued adult diseased RTT mice not only indicates that MECP2 is needed for normal adult function (Robinson et al, Brain 2012) but also that gene therapy might be beneficial for RTT patients, even after the disease has started.
AAV9 has been shown to cross the blood brain barrier (BBB) and infect brain cells after intravenous injection in both rodent and primates (Foust et al, Nat Biotech 2009; Duque et al, Mol Ther 2009; Gray et al, Mol Ther 2011).
We generated an AAV9 expressing GFP (control virus) or a codon-optimized version of Mecp2 under the regulation of the mouse Mecp2 promoter (named scAAV9-MCO) and confirmed their efficacy in vitro by infecting NIH/3T3 mouse fibroblasts and primary mixed neurons/glia cultures. Preliminary experiments investigating the efficacy and bio-distribution of these viruses in vivo after intravenous injection show that scAAV9 crosses the BBB, which is in agreement with results from other groups. Our next experiments will be aimed at the in vivo testing of both control and scAAV9-MCO virus in the RTT mouse model and the determination of a potential rescuing effect in these mice.

Rett syndrome (RTT,OMIM 312750) is a progressive neurologic developmental disorder mainly affecting females with an incidence of 1:10000. Clinical presentation appears very heterogeneous. "Classical" phenotype includes impaired communication and hand skills, stereotypic hand movements, and a gradual decrease in acquired gross motor abilities over time; among atypical variants the "Zappella variant shows more moderate traits, in presence of crucial diagnostic criteria. Mutations in the MECP2 gene is the most common cause of RTT. Out of a cohort of 138 girls with MECP2 mutation, we distinguished three mentally impaired patients with "high-functioning" phenotype, preserved hand skills and able to articulate even complex sentences; no microcephaly and clear regression were observed but occurrence of hand stereotypies or dyspraxic gait were suggestive of RTT. Molecular testing revealed two MECP2 mutations already described in Zappella-variant or mild phenotypes, while the third is a mutation reported in carriers males showing learning impairment and spasticity, who inherited the mutation from their unaffected XCI balanced mothers and in a mildly affected sporadic mental retardation- Non Rett syndrome female with completely skewed XCI. For two out of three patient we could perform mRNA investigation to confirm preferential expression of a single MECP2 allele. Our data underline the broad phenotypic spectrum of the MECP2 mutations and suggest to screen it in female patients with mental impairment and some features reminding of Rett syndrome

Rett syndrome is a monogenic disease due to de novo mutations in either *MECP2* or *CDKL5* genes on the X chromosome. In spite of their involvement in the same disease, a functional interaction between the two genes has not been proven. MeCP2 is a transcriptional regulator; *CDKL5* encodes for a kinase protein that might be involved in the regulation of gene expression. Therefore, we hypothesized that the two genes may lead to similar phenotypes by dys-regulating the expression of common genes. To test this hypothesis we used induced pluripotent stem (iPS) cells derived from fibroblasts of one Rett patient mutated in *MECP2* and 2 patients with mutations in *CDKL5*. Expression profiling was performed in *CDKL5*-mutated cells and genes of interest were confirmed by real-time RT-PCR in both *CDKL5* and *MECP2* mutated cells. The only major change in gene expression common to *MECP2*-mutated and *CDKL5*-mutated cells was for *GRID1*, encoding for glutamate d1 receptor (GluD1), a member of the delta family of ionotropic glutamate receptors. GluD1 ability to form functional AMPA or NMDA glutamate receptors has not been demonstrated. It acts like an adhesion molecule by linking the postsynaptic and presynaptic compartments and inducing excitatory and inhibitory presynaptic differentiation. Our results demonstrate that *GRID1* gene is down-regulated in both *MECP2*-mutated and *CDKL5*-mutated iPS cells and up-regulated in neuronal precursors, providing the first functional link between the two genes. These data provide novel insights into disease pathophysiology and identify possible new targets for therapeutic treatment of Rett syndrome.

Mutation analysis of MECP2, CDKL5, and FOXG1 genes in Czech patients with Rett syndrome and Rett-like phenotype

D. Zahorakova[1], *A. Puchmajerova*[1], *A. Baxova*[2], *P. Martasek*[1];
[1]*Department of Pediatrics, 1st Faculty of Medicine, Charles University in Prague and General Teaching Hospital, Prague, Czech Republic,* [2]*Institute of Biology and Clinical Genetics, 1st Faculty of Medicine, Charles University in Prague and General Teaching Hospital, Prague, Czech Republic.*

Rett syndrome is a severe X-linked dominant neurodevelopmental disorder affecting mostly females and primarily caused by de novo mutations in the MECP2 gene. It is characterized by developmental regression, acquired microcephaly, loss of purposeful hand use and speech, stereotypic hand movements, autistic features, gait apraxia, breathing anomalies, and seizures. Mutations in other genes have been identified in early-onset seizure variant (CDKL5) and congenital variant (FOXG1) of Rett syndrome. We report the results of molecular analysis of MECP2, CDKL5, and FOXG1 genes in patients with Rett syndrome and mental retardation with Rett-like features from Czech Republic.
MECP2 and CDKL5 were analyzed by high-resolution melting analysis and DNA sequencing of coding regions and exon/intron boundaries. FOXG1 was analyzed by DNA sequencing. Large deletions in all three genes were analyzed by multiplex ligation-dependent probe amplification.
We identified MECP2 mutations in 65 out of 86 patients with classic Rett syndrome (76%). 20 patients with Rett syndrome variants were initially screened for MECP2 mutations and 6 MECP2 mutations were identified (30%). The subsequent analysis of CDKL5 gene in patients with early-onset seizure variant revealed mutations in 2 cases (6,7%). No mutation has been identified in FOXG1 gene in the patients with congenital variant of Rett syndrome.
We confirmed the high frequency of MECP2 mutations in classic Rett syn-

drome. On the other hand, MECP2 mutations are not a frequent cause of early-onset seizure and congenital variant of Rett syndrome or mental retardation with Rett-like phenotype.
Supported by grants NT 13120-4/2012, MZCR RVO-VFN64165/2012, P24/LF1/3, and UNCE 204011/2012.

Astrocyte transcriptome from Mecp2-deficient mice: relevance to the pathogenesis of Rett syndrome

C. Delépine[1], *J. Nectoux*[1], *F. Letourneur*[1], *S. Reibel*[2], *J. Chelly*[1], *T. Bienvenu*[1];
[1]*Université Paris Descartes, Institut Cochin, INSERM U1016, Paris, France,*
[2]*Chronobiotron, IFR37, Strasbourg, France.*

Mutations in the *MECP2* gene cause the neurodevelopmental disorder Rett syndrome which is one of the most frequent causes of intellectual disability with genetic origin in women. Although MeCP2 levels are roughly five-fold lower in astrocytes than in neurons, recent studies showed that Mecp2 loss in astrocytes contributes to Rett-like symptoms and restoration of Mecp2 can rescue some of these defects. Moreover, mutant astrocytes have a non-cell autonomous effect on neuronal properties, probably resulting from aberrant secretion of soluble factor(s). To identify these soluble factors, we have compared the gene expression profiles of wild type and mutant astrocytes from Mecp2 $^{308/y}$ mice using Affymetrix mouse 2.0 microarrays. The results obtained were confirmed by quantitative real-time RT-PCR. A false discovery rate (FDR) of 0.05 was applied to the lists of differentially expressed genes between wild-type and mutated samples. 2152 genes passed the stringent FDR filter of 0.05 including 1784 coding transcripts. However, only 80 also had an expression fold change >1.25 in Mecp2 $^{308/y}$ cells versus Mecp2 $^{+/y}$ cells. Interestingly, among these genes, several genes encode secreted proteins such as myocilin, lipocalin 2, SHH or Wnt7b, implicated in neuronal maturation. Others contribute to major astrocytic functions such as the exocytotic release of glutamate (Slc17a8), glutamate metabolism(GAD1) and glucose metabolism (Adcy8, Acot4). We need to confirm these data at the proteomic level in astrocyte and conditional medium from symptomatic Mecp2-deficient mice. Therefore, insights into astrocyte secretion are critically important for understanding physiological responses and pathological mechanisms in Rett syndrome.

Simpson-Golabi-Behmel syndrome (SGBS), a rare X-linked MCA/ID syndrome, is characterized by pre- and postnatal overgrowth, distinctive craniofacial features, congenital malformations, visceromegaly, an increased risk of tumour and mild/moderate intellectual deficiency in some cases. In 1996, causative mutations were identified in the GPC3 gene mapping at Xq26 (major gene of SGBS). Since the first description, many other cases have been reported with a wide clinical range of symptoms and severity. Among them, a few cases were significantly different as they had atypical clinical presentation with more severe prognosis and/or numerous congenital malformations. However, these descriptions occurred before the availability of molecular analysis. Moreover the mutation detection rate in SGBS is only 37% to 70%, suggesting that some patients could have different disorders. Finally, in the family reported by Golabi and Rosen, a duplication of GPC4, mapping close to GPC3, was recently identified, suggesting that GPC4 could be the second gene for SGBS.
In order to better delineate the phenotypic spectrum of SGBS caused by GPC3 mutations, and to try to define specific clinical criteria for GPC3 molecular testing, we reviewed the clinical features of all male cases with a GPC3 mutation identified in the two molecular laboratories providing this test in France. A clinical questionnaire based on literature data was send to the referring physicians in order to collect relevant information i.e. family history, prenatal and postnatal data.
We present here the results of the clinical and molecular analysis of 42 patients including 8 foetuses or stillborn babies.

Characterization of novel "de novo" mutation in the *SLC6A8* gene

J. Aguirre-Lamban[1], *C. Cervera-Acedo*[1], *E. Sarasola*[2], *L. Calvo-Perez*[3], *A. Garcia-Oguiza*[3], *J. Garcia-Peñas*[4], *M. Garcia-Barcina*[2], *M. Poch Olive*[3], *E. Dominguez-Garrido*[1];
[1]*Fundacion RiojaSalud-CIBIR, Logroño, Spain,* [2]*Hospital de Basurto, Bilbao, Spain,* [3]*Hospital San Pedro, Logroño, Spain,* [4]*Hospital Niño Jesus, Madrid, Spain.*

Introduction: Cerebral creatine deficiency is an X-linked disorder caused by mutations in the *SLC6A8* gene (Xq28). It consists of 13 exons and encodes a protein of 635 amino acids. This disorder causes an increase of creatine levels in urine and plasma, and urinary creatine/creatinine ratio. The clinical presentation of males affected is mental retardation, expressive speech and language delay, epilepsy, developmental delay and autistic behaviour.
Subjects and Methods: An 8 year-old male patient presents learning difficulties, behaviour disorder and epilepsy. An increase of creatine/creatinine ratio, guanidineacetate and glycine levels (plasma and urine) was detected. The 13 exons of the *SLC6A8* gene, including the intron-exon junctions, were analyzed by PCR and direct sequencing reaction.
Results: We detected a 34 pb deletion (c.1016+11_1017-52del34) in intron 6, that was predicted to cause an aberrant splicing into acceptor splice-site. At the cDNA level, this mutation produces a 30 pb deletion in exon 7 and a single amino acid insertion (p. K339_S349delinsN). This variant was not detected in the mother and is therefore considered *de novo.*
Discussion: DNA and RNA analysis were necessary to characterize this novel pathogenic mutation. The detected change in the creatine transporter could be responsible for a lower and/or no activity of the protein. Functional studies in cultured skin fibroblasts will be necessary to show a deficiency of the creatine transporter function.

Characterisation of de novo dicentric supernumerary marker chromosome 15 (Prader-Willi / Angelman critical region included) in a boy with subtle phenotype

P. Tesner, *M. Vlčková, J. Drábová, V. Zimanová, E. Kočárek;*
Dept. of Biology and Medical Genetics, University hospital Motol and 2nd Faculty of Medicine, Charles University, Prague, Czech Republic.

Although it is estimated almost 3 million of people of the world population are carriers of supernumerary marker chromosomes (SMCs), only less than 5000 SMCs are reported in their largest database, Liehr´s SMC-homepage assembled in Universitätsklinikum Jena. More than every fifth gathered SMC is derived from chromosome 15, most of them in isochromosome 15 syn-

drome patients.
SMC(15)s containing Prader-Willi/Angelman critical region (PWACR, 15q11-q13) are usually associated with severe phenotype, according to N.R.Dennis et al. (2006): hypotonia, motor and speech delay, seizures, moderate to severe learning disability, and autism while dysmorphic features are absent or subtle, growth is usually normal.
We report a case of a 4-year-old boy with de novo dicentric SMC(15). The FISH analysis of this abnormal chromosome revealed two copies of PWACR region and only one signal of the acro-p-arm probe. The patient has short stature and suffers from moderate intellectual disability. He has no history of seizures and his muscle tone is evaluated as slightly decreased. J.A.Crolla et al. (2005) pointed out that SMC(15)s are the only SMCs, which incidence could be related to increased maternal age - our proband was born to 36-years-old mother.
Other analyses are to be done to define the exact range of this abnormal chromosome and to explain parental origin and DNA-methylation pattern of every individual copy of the critical region. Their results will be presented and discussed on the poster.
Our work is supported by Grant Agency of Charles University (No. 264811) and Technology Agency of the Czech Republic (No. TA01010931).

Silver-Russell syndrome (SRS) is a clinically and genetically heterogeneous syndrome characterized by intrauterine growth restriction, body asymmetry, relative macrocephaly and a triangular face. SRS is mostly caused by hypomethylation of the imprinting control region 1 (ICR1) on chromosome 11p15.5, but cytogenetic aberrations have also been described in sporadic cases. Microdeletions 15q26 including the *IGF1R* gene with clinical features overlapping with SRS have been reported few times in the literature.
Here, we report clinical and molecular findings in a 12-year-old boy with features suggestive of SRS. The MS-MLPA method did not reveal ICR1 hypomethylation. On the other hand array-CGH identified 3.37 Mb deletion in 15q26.3 causing *IGF1R* gene haploinsufficiency and 1.21 Mb duplication in 17q11.2 including region of the Neurofibromatosis 1 with intellectual disabilities with *NF1* gene.
Clinical features suggestive of SRS included small anthropometric parameters at birth (SGA) and lack of postnatal catch-up growth, feeding problems, gastro-esophageal reflux, dysmorphy including triangular and asymmetric face and micrognathia, as well as minor skeletal abnormalities. The discriminating feature was microcephaly, which has been described in cases with del15q26.3, carrying also characteristics overlapping with SRS, such as SGA, postnatal growth retardation and the triangular face. The del15q26.3, along with 17q11.2 duplication, could also contribute to motor and speech delay, as well as intellectual disability.
The presented case proves the array-CGH method is a powerful diagnostic tool confirming genetic etiology in patients with ambiguous phenotypes.
The study was supported by MNSW grant No_2853/B/P01/2010/39. The Roche NimbleGen microarray platform was co-financed by ERDF (EU_Structural_Funds) project POIG.02.01.00-14-059/09.

Early epileptic encephalopathy associated with STXBP1 mutations: could we better define the phenotype?

N. Chemaly[1], *G. Barcia*[1], *S. Gobin*[2], *M. Milh*[3], *P. Van Boggaert*[4], *A. Kaminska*[1], *O. Dulac*[1], *V. Cormier-Daire*[2], *N. Boddaert*[5], *R. Nabbout*[1];
[1]*Department of Neuropediatrics, Inserm U663, hôpital necker enfants malades, Paris, France,* [2]*Department of Genetics, Inserm U781, hôpital necker enfants malades, Paris, France,* [3]*Department of Neuropediatrics, Hopital La Timone, Marseille, France,* [4]*Department of Neuropediatrics, Hopital Erasme, Bruxelles, Belgium,* [5]*Department of Pediatric Radiology, hôpital necker enfants malades, Paris, France.*

STXBP1 (Munc18.1), encoding syntaxin binding protein1, is a new gene causing epileptic encephalopathy. Mutations in STXBP1 have been first reported in early onset epileptic encephalopathy with suppression-bursts, then in infantile spasms and, more recently, in patients with non syndromic mental retardation without epilepsy.
To better define the clinical phenotype and to determine the occurrence of specific neuroradiological abnormalities in patients with STXBP1 mutations, we analyzed clinical and neuroradiological findings in a series of patients having STXBP1 mutations.
We included patients with STXBP1 abnormalities followed at our institution and who underwent a high resolution brain MRI.
We identified 7 unrelated children (6 females, 1 male) with STXBP1 mutations. Age at seizure onset ranged from 1 day to 3 months. All children presented with infantile spasms and 5 had a suppression-burst pattern on EEG. Although all patients were seizure free before the age of 2 years, they showed global and severe developmental delay. Neuroimaging analysis showed a peculiar aspect of thin and dysmorphic corpus callosum associated with cortical frontal atrophy.
STXBP1 mutations are detected only in a minority of patients with early epileptic encephalopathy. We suggest that patients with thin corpus callosum and frontal cortical atrophy on brain MRI, especially if seizures are controlled in the first years, could represent the best candidate to genetic analysis of STXBP1.

Intellectual disability (ID) is frequent in the general population, with 1 in 50 individuals directly affected worldwide. The multiple etiologies include X-linked ID (XLID). Among syndromic XLID, few syndromes present severe ID associated with postnatal microcephaly and midline stereotypic hand movements. We report on two male patients with ID, non inherited and postnatal onset microcephaly, midline stereotypic hand movements, hypotonia, hyperkinesia, strabismus, as well as seizures for one of the patients. Using array-CGH and exome sequencing we characterized two truncating mutations in IQSEC2, namely a de novo intragenic duplication mapped to the Xp11.22 region and a nonsense mutation in exon 7. We propose that truncating mutations in IQSEC2 are responsible for syndromic severe ID in male patients and should be screened in patients without mutations in MECP2, FOXG1, CDKL5 and MEF2C.

SYT1 is an essential regulator of fast, synchronous vesicle exocytosis. We report the first case of a human disorder associated with SYT1 mutation. The clinical features are severe dyskinetic movement disorder and profound cognitive impairment. Epileptic seizures have not been observed and clinical MRI is normal. EEG demonstrates extensive low-frequency oscillations, abnormal paired-pulse depression of visual evoked potentials, and immatu-

re auditory evoked potentials. Whole exome sequence analysis revealed a de novo missense mutation (I368T) at a functionally-critical residue in SYT1. This case suggests that activity-dependent regulation of vesicle release is necessary for motor control and for emergence of higher cognition.

Differential expression of the Ubiquitin-conjugating genes (E2) during the differentiation of hippocampal neurons and after stimulation by NMDA

A. Paubel[1,2], *P. Vourc'h*[3,2], *S. Tourlet*[3], *C. Michelle*[4], *G. Bouchez*[4], *J. Colas*[4], *J. Tastet*[4], *S. Marouillat*[4], *S. Segura*[4], *F. Laumonnier*[4], *C. R. Andres*[3,2];
[1]*Service de Génétique, Hôpital Bretonneau, CHRU de Tours, TOURS, France,* [2]*INSERM U930, Université François-Rabelais, Tours, France,* [3]*Laboratoire de Biochimie et Biologie moléculaire, Hôpital Bretonneau, CHRU de Tours, TOURS, France,* [4]*INSERM U930, Université François-Rabelais, TOURS, France.*

The Ubiquitin pathway controls protein stability and signalling during neuronal development, maturation and plasticity. Mutations in genes encoding Ubiquitin-conjugating enzymes (E2) and Ubiquitin-ligases (E3) have been described in neurodevelopmental diseases (i.e. UBE2A in XLMR, UBE3A in Angelman syndrome for example).
We identified 38 E2 genes in the Human genome, 39 in the Mouse genome (Michelle et al., 2009). To better understand their role during brain development and function we analyzed their expression during the differentiation of hippocampal neurons in vitro and after stimulation. RT-QPCR analyses were performed on RNA extracted from primary cultures of hippocampal neurons from mouse embryos (E17). A large majority of the 39 E2 genes were expressed during the differentiation of hippocampal neurons, and interestingly their expression varied with the stage of differentiation and maturation. Moreover, we observed important variations of expression for several E2 genes after N-methyl-D-aspartate (NMDA) stimulation. Using in silico analysis, we identified several potential binding sites for neural transcription factors, such as Creb1, Pdx1, Runx1, in the promoters of many E2 genes.
The variations of expression coupled with the presence of potential binding sites for transcription factors important during brain development gave insight into the regulation and the roles of E2 genes in neurons. These results support further studies on E2 genes in neurodevelopmental diseases such as intellectual disability.

West syndrome is characterized by the association of infantile spasms with an age onset between 3 and 7 months, characteristic EEG pattern (hypsarrythmia) and developmental delay. Incidence is 1/6000 and unfavourable outcome is observed in 80% of patients. Etiologies are numerous, acquired or congenital, including genetic anomalies. Genetic causes include Down syndrome, 1p36 deletion, tuberous sclerosis and mutations in ARX or CDKL5 genes. However, 50% of the patients remain without etiological diagnosis. Knowledge of etiological diagnosis is critical because it represents a major prognostic factor and underlies the possibility for genetic counselling.
We present the molecular analysis of 73 patients with West syndrome or infantile spasms without etiological diagnosis. aCGH was performed and 5 genes were screened : CDKL5, STXBP1 and KCNQ2 for their implication in early epileptic encephalopathy, GRIN2A and MAGI2, candidate genes from the literature.
We found 2 mutations in CDKL5 including an atypical case of 2 mosaic populations and 3 mutations in STXBP1. All of these were de novo. Among other anomalies, aCGH found 3 deletions (one of 10Mb in 2q24.3, one of 3,24Mb in 5q14.3 including region up to MEF2C, one of 256 kb in 9q34 corresponding to the Kleefstra syndrome), and 2 duplications (one of 671 kb including SCN2A gene and one of 11.93 Mb in Xq28).
So, 13.6% of our cohort presented pathogenic mutations. These concerned the most severe patients, most of which presented a history of neonatal seizures. These results stress the importance of genetic screening for patients with West syndrome.

Williams Syndrome (WS) is a developmental neurogenetic disorder caused by hemizygous deletion at 7q11.23, distinguised by a characteristic neurocognitive profile wich include intellectual disability (ID). Haploinsufficiency of some genes in the region has been associated with the cognitive phenotype. ID is difficult to address because of multiples etiologies, intrinsic complexity in neural tissue and high degree of regulation in neural development and function. The aim of this work is to determine if there are differences in the expression of microRNAs in neural cells derived from olfactory neuroepithelium of patients with WS in regards to controls, and to assess its possible involvement in neurodevelopment or neural function. Relative expression was assessed by Real-time PCR, using the TLDA Human MicroRNA Panel v2.0 (Applied) and prediction for potential neural targets and pathways involved, by in silico analysis (software TargetScan, miRecords and PITA Top Targets). Results show 15 deregulated microRNAs (3 over-expressed and 12 under-expressed), wich themselves include brain rich miRNAs as miR-32, miR-125b, let-7c and miR200, and others previously reported with specific neural functions or deregulated in brain diseases. For the majority potential targets were found associated with neural developmental pathways and function or other entities that present with intellectual disabilities. These data suggest miRNAs contribute greatly in regulating intrinsic neurodevelopmental processes and that specific miRNAs could be involved in various molecular pathways in the neurobiology of WS.

Exploration of Williams-Beuren syndrome-like cases

S. Bezieau[1], *S. Küry*[1], *B. Leheup*[2], *B. Isidor*[1];
[1]*CHU Nantes, Service de Génétique Médicale, Nantes, France,* [2]*CHU Nancy, Service de Médecine Infantile, Vandoeuvre-Lès-Nancy, France.*

Background: Williams-Beuren syndrome (WBS; OMIM#194050) is a rare genetic disorder characterized by an abnormal development expressed by congenital heart defects, suggestive facial dysmorphy, as well as cognitive and behavioural impairments. About 95% of WBS cases are due to a 1.5 to 1.8 microdeletion of chromosomal region 7q11.23, containing 26 to 28 genes. The remaining 5% of cases, which cannot be explained by a contiguous-genedeletion syndrome, may be classified as WBS-like cases.
Purpose: We focused on patients with a WBS-like disorder to determine the molecular cause of these atypical forms.
Method: Seven individuals of three different WBS-like families were tested by whole-exome sequencing: two trios composed by a male patient and his asymptomatic parents, and a third female patient. *De novo*, X-linked and recessive mutations were searched in patients of trios, and their variants were compared to the ones observed in the third patient. A fourth WBS-patient was subsequently tested by Sanger sequencing for mutations in candidate genes.
Results: Predicted deleterious mutations very likely related to their disorder were found in the two patients from trios, yet none in a common gene. No

potentially pathogenic variant were found in the third and fourth patients in inferred candidate genes.
Conclusions: Our study points to the genetic heterogeneity of Willams-Beuren-like syndrome. It highlights however strong candidate genes, which might contribute to a better understanding of WBS pathogenesis. Additional cases would need to be tested to confirm our present observations.

P05.137

Partial monosomy 1q23 associated with severe seizures and profound mental retardation due to a mosaic translocation (1q,16q) (q23; qter)

E. Sukarova-Angelovska, M. Kocova, G. Ilievska, N. Angelkova, S. Palcevska, ***E. S. Stefanovska****;*
Pediatric Clinic, Skopje, Macedonia, The Former Yugoslav Republic of.

Reciprocal translocations are common cytogenetic anomalies occurring with frequency of about 1 in 500 births. Mosaic state of the translocation is a rare event which indicates that the breakage occurred in the first mitotic divisions of the zygote. Sometimes a certain amount of DNA within the breakage region could be lost and determines clinical presentation depending on the lost genes. A newborn girl have been evaluated because of poor sucking and dysmorphism. It was the first child in the family. Diminished fetal movements and intrauterine growth retardation were noticed. The baby was full-term neonate with birth weight and length under 3rd percentile. Dysmorphic features were present - narrow forehead, hypotelorism, ptosis, telecantus, micrognathia, low-set simple ears. Hemangioma of lumbosacral region was present. Hypotonia, brisk reflexes were present, primitive reflexes persist after 6 months. At the age of 3 months she developed refractory generalized seizures. MRI showed global cortical atrophy, especially in frontal and temporal areas. Anticonvulsive drugs had poor effect. At the age of 1 year the girl have profound mental retardation. Chromosomal finding showed translocation between chromosomes 1q and 16q in 50% of the analyzed mitoses; the rest of the cells showed normal karyogram. FISH for subtelomeric ragions on 1q and 16 q were present on marker chromosome 16. The breakpoint was on 1q23 with probable microdeletion in that region. There are several genes within the region that could be disrupted by the deletion, therefore further investigation is needed to acquire the exact cause of disorganized cortex.

P05.138

CGH analysis in a cohort of 54 males with unexplained X-linked intellectual deficiency.

C. Mignon-Ravix*[1,2], P. Cacciagli[1,3], S. Sigaudy[3], C. Badens[1,2,3], N. Philip[1,2,3], L. Villard[1,2];*
[1]Inserm UMR_S 910, Marseille, France, [2]Aix Marseille Université, Marseille, France, [3]Génétique Médicale et Biologie Cellulaire, CHU Timone Enfants, Marseille, France.

In order to assess the presence of submicroscopic deletions/insertions in X-linked genes, we screened a cohort of 54 male individuals suffering from moderate to severe intellectual disability using custom-designed Roche Nimblegen 720K oligonuclotide array CGH. These individuals were selected in families were the phenotype is transmitted through unaffected (or mildly affected) carrier females. Our custom arrays contain 720,000 probes with average probe spacing across the X chromosome of 50bp in genic regions and 20kb and intergenic regions.
We found 70 copy number variations (CNVs) affecting the X chromosome in this cohort. The CNVs were all confirmed using Q-PCR. 42 CNVs are known in the control population, including 20 CNVs located in the pseudoautosomal region. 28 CNVs are unknown in variation databases (17 deletions, 8 duplications, 3 found both deleted and duplicated in our cohort). Among these later cases, 8 CNVs are located in the pseudoautosomal region. For the 20 remaining CNVs, 15 are located in introns and 5 affect exons of 17 different X-linked genes. Two CNVs affecting already known XLID genes (IL1RAPL1 and OPHN1) were considered to be pathogenic. We identified 4 « potentially pathogenic » aberrations, involving genes not yet implicated in XLID but considered as new candidate genes for intellectual disability.

P05.139

Difficulties in screening small families with X linked Intellectual disability

I. REJEB*[1], L. BEN JEMAA[1], L. KRAOUA[1], M. CHOGRANI[1], H. JILANI[1], F. MAAZOUL[2], J. CHELLY[3], H. CHAABOUNI[1,2];*
[1]Department of Human Genetics Faculty of Medicine, Tunis, Tunisia, [2]Department of Hereditary and Congenital Diseases, Tunis, Tunisia, [3]Institut Cochin, Université Paris-Descartes, CNRS (UMR 8104); INSERM U1016, Paris, France.

Intellectual disability (ID) is characterized by significant limitations in cognitive abilities and social/behavioural adaptive skills. It is estimated that 1-3% of the general population is affected with ID. Intellectual disability is one of the primary reasons for paediatric, neurologic, and genetic referrals. We investigated 3 families with mentally retarded males, clinical examination, cytogenetic and molecular studies and basic metabolic screening were performed.
We identified in each family a mutation in X-linked genes. The mutations were a splice mutation in PAK3 gene, a frame shift mutation in PQBP1 gene and a missense one in NHS gene. All the founded mutations that segregate with intellectual disability were described for the first time.
Despite the fact that our families were small, a mutation was identified each time. This is due to the fact that a good clinical examination was performed first followed by good literature search which was essential to compare the clinical features of our families to those reported in the literature. This highlights the importance of clinical data in genetic linkage studies. Our study shows that in a lack of large families, small families like ours can be interesting to study.

P05.140

X-exome analysis detects novel mutations in XLID genes in a cohort of male patients with intellectual disability

A. Tzschach*, C. Dufke, C. Bauer, M. Kehrer, U. Grasshoff, A. Riess, M. Sturm, C. Schröder, A. Dufke, O. Riess, P. Bauer;*
University of Tuebingen, Tuebingen, Germany.

Intellectual disability (ID) has a prevalence of 1-3 % and is a major medical problem. Mutations in X-chromosomal genes are estimated to account for approximately 10 % of male ID patients. Apart from fragile X syndrome, which is at cause in about 25 % of X-linked ID (XLID) and which has been part of the routine diagnostic work-up for many years, more than 90 other XLID genes are known to date. The low prevalence of mutations in each individual gene has, however, rendered routine testing of these genes impractical in patients with unspecific clinical features.
The advent of new sequencing technologies has enabled us to establish a platform combining in-solution enrichment of the coding regions of all XLID genes and subsequent next-generation sequencing (NGS). We have employed this XLID panel for analyzing a cohort of more than 120 unselected male ID patients in whom chromosome aberrations and fragile X syndrome had already been excluded. As a result, we found unambiguously disease-causing mutations in genes such as ATRX, MED12, CUL4B, DLG3, SLC9A6, KDM5C and UBE2A in more than 5% of the patients, and variants of unclear pathogenicity were present in additional patients. Considering the high recurrence risks for X-linked disorders, XLID panel analysis has thus been shown to be a valuable diagnostic tool in male patients with non-syndromic or atypical syndromic ID.

X-linked mental retardation (XLMR) is the most common form of mental retardation in males. Syndromic MR encompasses intellectual disability deficits associated with other medical and behavioral symptoms. Recently, a large Sardinian family with a novel form of syndromic XLMR was characterized. Eight of 24 members of the family are male and have MR, short stature, aphasia, skeletal abnormalities and dysmorphic features. Previous linkage studies identified a region of 16 cM around DXS1001 in Xq24 with

a maximum Lod score of 3.61. Whole-exome sequencing was performed on the parents, three affected sons and one unaffected daughter. One SNP was found in the 3'-UTR of the ZBTB33 (Kaiso) gene which maps within the previously associated region of linkage and segregates with the disease phenotype in the family. This SNP was not found in 30 unrelated control samples. Kaiso binds to methylated DNA, represses target genes in the Wnt signaling pathway and is highly expressed in the brain. The SNP creates a binding site for miR-4999 and miR-4774; however, luciferase expression assays failed to validate increased targeting of these miRs to the variant 3'-UTR. This SNP may affect 3'-UTR structure leading to decreased mRNA stability, or the SNP may be closely linked to the disease-causing mutation, which is not located in an exon. While the functional consequences of this base change are not yet known, our results implicate this region as a new locus for XLMR.

Non-syndromic X-linked intellectual disability caused by a missense mutation in *RPS6KA3*, the gene responsible for Coffin-Lowry syndrome

A. B. Sousa[1], *J. Dupont*[1], *V. M. Kalscheuer*[2], *A. Medeira*[1], *A. P. M. de Brouwer*[2,3], *I. Cordeiro*[1];
[1]*Serviço de Genética, Departamento de Pediatria, Hospital de Santa Maria/CHLN, Lisboa, Portugal,* [2]*Max Planck Institute for Molecular Genetics, Department of Human Molecular Genetics, Berlin, Germany,* [3]*Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.*

Coffin-Lowry syndrome (CLS) is a rare X-linked intellectual disability disorder caused by mutations in *RPS6KA3*, which encodes RSK2, a growth factor-regulated protein kinase acting in the MAPK signaling pathway. Affected males usually present with severe intellectual disability and characteristic facial and hand features allowing a gestalt diagnosis. The face coarsens over time and typically includes a prominent forehead, hypertelorism, narrow downward slanting palpebral fissures, anteverted nares, thickened alae nasi and nasal septum, and wide mouth with thick everted lips. The hands are broad and soft with stubby tapering fingers. Additional CLS features include short stature and progressive scoliosis.
We describe three boys with non-syndromic intellectual disability in a family with a pattern compatible with X-linked transmission. Sequencing of all exons on the X-chromosome identified a missense mutation, c.646A>G (p.Lys216Glu), in *RPS6KA3* (NM_004586.2) that segregated with the phenotype in the family. Two of the patients were reassessed a posteriori and found to have subtle facial CLS features (narrow palpebral fissures, broad based nose with thick septum and alae nasi, and slightly everted lower lip), uncharacteristic digits, normal growth and no spinal deformity. Several clinical geneticists agreed that the diagnosis of CLS would not easily be considered on clinical grounds. A few other such cases have been reported, also caused by proximal missense mutations or small in frame deletions. Together these patients illustrate the potential spectrum of clinical variability in CLS and the power of massive parallel sequencing to produce etiological diagnosis in situations of wide genetic heterogeneity.

'A frameshift mutation in the ubiquitinylation-related gene KLHL15 causes a novel X-linked intellectual disability syndrome associated with hypogenitalism, short feet and hypoplastic alae nasi'

M. Badura-Stronka[1,2], *B. Budny*[3], *H. Hu*[4], *S. A. Haas*[5], *T. Żemojtel*[5], *M. Raynaud*[6], *R. Glazar*[2], *H. H. Ropers*[4], *A. Latos-Bieleńska*[1,2], *V. M. Kalscheuer*[4];

X-linked intellectual disability (XLID) is a clinically complex and genetically heterogeneous group of disorders with a growing number of disease-associated proteins implicated in ubiquitin-mediated proteolysis. To date, three XLID genes involved in the ubiquitination pathway have been identified on the X-chromosome (*CUL4B*, *UBE2A*, *HUWE1*). We report a four-generation family with 7 affected males with mild to moderate intellectual disability, small penis and testes, very short, flat feet, and relatively mild dysmorphic features including flat philtrum, thin upper and prominent lower lip, straight nose with hypoplastic alae nasi, micrognathia and deep-set eyes. Massively parallel sequencing of all X-chromosome specific exons in the index patient identified a frameshift mutation in *KLHL15* which resulted in a premature stop codon. This mutation co-segregated with XLID in the family. These findings were concordant with previous linkage results showing a significant LOD Score in the *KLHL15* containing region Xp22.22-Xp22.11. X-inactivation studies in female carriers, who are all asymptomatic, revealed an extremely skewed X-inactivation profile in their blood lymphocytes. *KLHL15* encodes an E3 ubiquitin ligase adaptor, which has been recently shown to promote the turnover of a brain-specific PP2A regulatory subunit by ubiquitylation and proteasomal degradation. Our results endorse further need for focusing on ubiquitination as an important contributor to intellectual disability.

Investigation of the interstitial microduplication of Xp22.31 with array-CGH

A. Alexandrou[1], *M. Moutafi*[1], *P. Antoniou*[1], *P. Evangelidou*[1], *V. Anastasiades*[2], *C. Sismani*[1], *P. C. Patsalis*[1];
[1]*The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus,* [2]*Arch Makarios III Hospital, Nicosia, Cyprus.*

The pathogenicity of the Xp22.31 duplication is a debatable subject amongst several authors. Some describe the microduplication as pathogenic; others as a normal variant whilst others remain unclear about its clinical significance. The region contains 7 genes: STS, VCX, VCX3A, VCX2, MIR4767, HDHD1A, PNPLA4. Here we present our findings after investigation of two cases where the same microduplication of Xp22.31 region was detected. The first case involves a 12 year old boy with Intellectual Disability (ID). Array-CGH was performed using Cytochip BAC array (BlueGnome) and revealed a duplication of approximately 2 Mb on the region of Xp22.31. The duplication was suspected to be causative for the phenotype. The duplication was present in the patient's mother and grandmother. The second case was a female carrier of the same duplication, detected using Cytochip ISCA array (BlueGnome). QRT-PCR revealed the same duplication in the carrier's mother.
Both have normal phenotype. X-inactivation was determined by methylation analysis for the androgen receptor (AR) locus and revealed skewed X-inactivation pattern for the mother and a normal pattern for the carrier. All male family members tested did not have any copy number gain. To further define the breakpoints, Chromosome X exon specific array, designed by Oxford Gene Technology (OGT) was used. Based on the current literature, there is a possibility that this duplication is predisposing to the onset of developmental delay and ID, possibly having an additive effect or represents a very rare population variant. Therefore genetic counselling for the Xp22.31 microduplication poses great challenges.

P05.145

A *de novo* loss of function mutation in an individual with short stature, microcephaly and ID establishes *ZNF238* as a candidate gene for the 1q43q44 microdeletion syndrome and Floating-Harbor like syndrome

S. A. de Munnik[1], *S. García-Miñaúr*[2], *B. W. van Bon*[1], *K. M. Boycott*[3], *C. Gilissen*[1], *A. Hoischen*[1], *J. Schoots*[1], *L. H. Hoefsloot*[1], *N. V. A. M. Knoers*[4], *H. G. Brunner*[1], *E. M. H. F. Bongers*[1];
[1]*Radboud University Medical Centre, Nijmegen, Netherlands,* [2]*Hospital Universitario La Paz, Madrid, Spain,* [3]*Children's Hospital of Eastern Ontario, Ottawa, ON, Canada,* [4]*University Medical Centre Utrecht, Utrecht, Netherlands.*

Floating-Harbor syndrome is an autosomal dominant disorder caused by mutations in *SRCAP*, and is characterized by short stature, speech delay, intellectual disability, and distinctive facial features. At present, mutations in *SRCAP* have been identified in nineteen individuals with Floating-Harbor syndrome. The phenotype of individuals with a chromosome 1q43q44 microdeletion consists of intellectual disability with limited or no speech, growth retardation, microcephaly, recognizable facial features, seizures, and agenesis of the corpus callosum. Several candidate genes for microcephaly, agenesis of the corpus callosum, and/or seizures have been proposed in literature, including *ZNF238*. So far, however, no mutations in this gene have been described.
We performed exome sequencing in an individual with a phenotype resembling Floating-Harbor syndrome, and her parents. The phenotype of

the girl comprised intellectual disability with speech delay, short stature, microcephaly, and dysmorphic facial features. A *de novo* nonsense mutation in *ZNF238* was detected: 397G>T (p.(Glu133)).
Sequencing in ten individuals with a similar phenotype revealed no additional mutations in *ZNF238*.
We present the first individual with a mutation in *ZNF238* with phenotypic overlap with the 1q43q44 microdeletion syndrome and Floating-Harbor syndrome. We propose *ZNF238* as the candidate gene for the phenotype of the 1q43q44 microdeletion syndrome and Floating-Harbor-like syndrome. More individuals with mutations in *ZNF238* need to be identified to support our findings and further delineate the clinical phenotype. *s.demunnik@gen.umcn.nl*

P06.01

Familial segregation of 15q11.3-13.3 duplication: phenotypic variability and lack of association with depression.

C. du Souich[1,2], *B. Millar*[1,2], *M. S. Peñaherrera*[3], *P. Eydoux*[4], *W. P. Robinson*[3], *C. F. Boerkoel*[1,5];
[1]*University of British Columbia, Vancouver, BC, Canada,* [2]*The Rare Disease Foundation, Vancouver, BC, Canada,* [3]*Department of Obstetrics and Gynaecology, University of British Columbia, Vancouver, BC, Canada,* [4]*Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada,* [5]*NIH Undiagnosed Diseases Program, Bethesda, MD, United States.*

We report a 3 generation family segregating a 15q11-q13 duplication with variable expressivity and lack of association with depression.
The proband presented with severe clinical depression, aggression and intellectual impairment. Comparative genomic hybridization showed a duplication at 15q11.2-q13.1. A similarly affected sister (autism spectrum disorder, anxiety and intellectual impairment) and their clinically depressed mother also carried the duplication. The mother has normal intellect. Another clinically depressed sibling with normal intellect did not carry the duplication. Methylation studies showed that the duplication had been inherited from the maternal grandfather who had normal intellect and absence of psychiatric disease.
Duplication of 15q11-q13 has previously been associated with cognitive impairment, autism, and psychiatric disease. Furthermore, the maternally inherited duplication most likely confers this phenotype whereas paternally derived duplications primarily show normal phenotypes.
Our family provides additional evidence that autism, psychiatric disease and intellectual disability segregate with a maternally inherited duplication at 15q11-q13 although with variable presentation. The presence of depression in the non carrier sister however, suggests a lack of association between clinical depression and the chromosomal duplication in this family, providing evidence that this duplication does not play a strong role in depression.

Since the advent of array-CGH, numerous new microdeletional syndromes have been delineated. We report on the first clinical delineation of 7 patients with interstitial deletions restricted to 3q28q27.3 gathered through the Decipher database and suggest this existence of a new microdeletional syndrome. The patients shared a recognisable facial dysmorphism psychiatric troubles and intellectual disability of variable intensity, associated with marfanoid habitus in the majority of patients. Delay in gross psychomotor acquisition was not systematically noticed; contrasting with severely impaired communicative skills with speech delay and psychiatric troubles. Skeletal manifestations, when present, included scoliosis, arachnodactyly, or feet anomalies, pectus excavatum, flat feet, long and thin habitus with low BMI. Two smallest regions of overlap were defined. The first one, on the 3q27.3 locus, was common to all patients and associated with bipolar troubles with psychotic manifestations and facial dysmorphism. It includes several candidate genes (MASP1, ADIPOQ, and SST), and SST seemed especially relevant because of its implication in interneurons migration and differentiation, frequently altered in schizophrenia. A familial case with a smaller deletion permitted to define the second region outside their interval, associated with severe intellectual disability, marfanoid habitus, long and thin habitus, and localised on the 3q27.2 locus, notably containing the AHSG gene. The AHSG gene encodes a secreted protein implicated in bone maturation, TGFb signalling pathway, and was associated to leanness in several studies. In conclusion, we report on a putative new microdeletional syndrome associating intellectual disability, bipolar disorder with psychosis, a recognisable facial dysmorphism and marfanoid habitus.

Genetic bases of Attention Deficit Hyperactivity Disorder (ADHD) in 300 Spanish patients: Preliminary results.

C. Gomez-Sanchez[1], *R. Riveiro-Alvarez*[1], *P. Tirado Requero*[2], *V. Soto Insuga*[1], *M. Rodrigo Moreno*[1], *M. Prados Alvarez*[3], *A. Segura Frontelo*[4], *J. Carballo Belloso*[1], *C. Ayuso*[1];
[1]*Instituto de Investigación Sanitaria Fundación Jiménez Díaz (IIS-FJD), Madrid, Spain,* [2]*Hospital Universitario la Paz, Madrid, Spain,* [3]*Hospital Universitario Infanta Elena, Madrid, Spain,* [4]*Hospital Rey Juan Carlos, Madrid, Spain.*

Aim: The purpose of this study is to preliminary describe the information available on the main group of genes that have been related with a susceptibility to Attention Deficit Hyperactivity Disorder.
Patients and Methods: 304 Spanish patients (between 6 and 17 years old) with clinical diagnosis of ADHD were evaluated over the following scales: ADHD Rating Scale-IV, Apgar Family function test, Parents-Rated Strengths and Difficulties Questionnaire, Children´s Depression Inventory, Children´s Global Assessment Scale and Clinical Global Impression.
Patients were genotyped for 7 genetic variants in genes in the dopaminergic system (DRD4: Exon 3-48bp VNTR, 5´120bp duplication; DAT1: 3´UTR 40bp VNTR; and DRD2: rs1800497), in the serotonergic system (SLC6A4: VNTR intron 2) and the latrophilin 3 gene (LPHN3: rs1397548, rs2305339). Allelic frequencies were assessed and compared to data reported in Caucasians, using chi-squared test.
Results: For all the above-mentioned variants, allelic association analysis showed no significant differences between Spanish patients with ADHD and control population: Exon 3-48bp VNTR (p=0.846), 5´120bp duplication (p=0.09), rs1800497 (p=0.559), 3´UTR 40bp VNTR (p=0.147), VNTR intron 2 (p=0.862), rs1397548 (p=0.076) and rs2305339 (p=0.699).
Conclusions: Although in recent years there has been an increase in the number of genetic studies conducted on ADHD, findings differ significantly from one study to another. Our preliminary results suggest the need of: 1) examination of refined phenotypes; 2) recruitment of control population matched for sex, age, and in which ADHD symptoms have been specifically excluded. Therefore, these considerations may reduce the heterogeneity and help to provide enough statistical power to these association

Genetics of Attention-deficit/hyperactivity disorder in the Portuguese population: candidate genes from GABAergic system

A. Marques[1], *S. Faria*[1], *J. Boavida*[2], *S. Nogueira*[2], *C. Alfaiate*[2], *M. Almeida*[2], *A. M. Cardoso*[1,3];
[1]*Clinical and Molecular Genetics Unit of the National Institute of Legal Medicine and Forensic Sciences, Coimbra, Portugal,* [2]*Child Development Center of Coimbra Children´s Hospital, Coimbra, Portugal,* [3]*IBILI-Faculty of Medicine of University of Coimbra, Coimbra, Portugal.*

Attention-deficit/hyperactivity disorder (ADHD) is a frequent childhood-onset psychiatric disorder and despite its high prevalence and heritability

the identification of ADHD risk genes has been challenging. Recent evidences suggest that dysfunctions in the GABAergic neurotransmission might be implicated in the etiology of ADHD, namely through genes encoding the GABA A receptors. Since no genetic studies have addressed this hypothesis, the current study aimed to investigate whether polymorphisms in GABRG2 (G3145A) and GABRA1 (A15G) genes are associated with ADHD in a sample of the Portuguese population. Blood samples were acquired from parents-offspring trios consisting of two parents and respective offspring, diagnosed with ADHD according to DSM-IV-TR, and genomic DNA was extracted from leukocytes through an enzymatic procedure. The GABRG2 G3145A and GABRA1 A15G polymorphisms were investigated by PCR-RFLP. We used either haplotype relative risk (HRR) and transmission disequilibrium test (TDT) and both strategies found no biased transmission of the alleles of GABRG2 G3145A polymorphism (HRR: $\chi2 = 0.104$, P = 0.747; TDT: $\chi2 = 0.047$, P = 0.829) and GABRA1 A15G polymorphism (HRR: $\chi2 = 0.426$, P = 0.514; TDT: $\chi2 = 0.275$, P = 0.600). The results seem to contradict the role of GABRG2 G3145A and GABRA1 A15G polymorphisms in the pathophysiology of ADHD in the Portuguese population. However, additional studies using a larger sample are being carried out to strengthen these preliminary results. This work was supported by the Portuguese Science and Technology Foundation (PhD grant SFRH/BD/69270/2010).

[1]*Department of Biotechnogy,University of Western Cape, Private Bag X17, Bellville 7535, South Africa, South Africa,* [2]*Computational Bioscience Research Center, King Abdullah University of Science and Technology, Thuwal 2355-6900, Kingdom of Saudi Arabia, Saudi Arabia.*

Background : Autism is genetically inherited neurodevelopmental disorder characterized by significant impairments of social interaction, difficulties in communication and displays of restrictive or repetitive behaviors activities and interests. Genome scan data have pointed towards the long arm of chromosome 7 as a strong candidate region. Various association and linkage studies are being undertaken in order to screen candidate genes mapping to the long arm of chromosome 7 as susceptibility loci. The anhydrolase domain containing 11 gene (ABHD11) is located on 7q11.23 which is a hotspot region for autism. This gene has not been investigated for its association to autism. Aims : The aim of this study was to investigate the association of two SNPs from genes ABHD11 (rs2293484 and rs10279013) in South African autistic population.Methods : A total of 435 individuals were recruited including 217 autistic and 218 control subjects. The Taqman ®Real-Time PCR and geno typing assay was utilized to determine the genotypes. Results: A significant association of SNP rs10279013 but not for SNP rs229348 with autism in the South African (SA) population is observed. Conclusion: There might be a possible role of ABHD11 in autism especially for SA populations. The present study represents the first report on genetic association studies on ABHD11 gene in SA population

P06.06
CNV characterization, inheritance and phenotypic correlations in families with autism

I. C. Conceição[1,2,3], *C. Correia*[1,2,3], *B. Oliveira*[1,2,3], *M. M. Rama*[1], *C. Café*[4], *J. Almeida*[4], *S. Mouga*[4,5], *F. Duque*[4,6], *G. Oliveira*[4,5,7], *A. M. Vicente*[1,2,3];
[1]*Instituto Nacional de Saúde Doutor Ricardo Jorge, Lisbon, Portugal,* [2]*Center for Biodiversity, Functional & Integrative Genomics, Lisbon, Portugal,* [3]*Instituto Gulbenkian de Ciência, Oeiras, Portugal,* [4]*Unidade Neurodesenvolvimento e Autismo, Centro de Desenvolvimento, Hospital Pediátrico (HP), Centro Hospitalar e Universitário de Coimbra (CHUC), Coimbra, Portugal,* [5]*Instituto Biomédico de Investigação em Luz e Imagem, Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal,* [6]*Faculdade de Medicina da Universidade de Coimbra, Coimbra, Portugal,* [7]*Centro de Investigação e Formação Clinica do HP-CHUC, Coimbra, Portugal.*

In this study, we characterized potentially pathogenic CNVs in a sample of 342 Portuguese children with Autism Spectrum Disorders (ASDs), genotyped by the Autism Genome Project whole genome CNV analysis. We selected high confidence CNVs (detected by 3 algorithms) not overlapping more than 20% with CNVs in 8000 controls.
We identified 165 CNVs in 132 individuals, 78% with only one CNV. CNVs ranged from 5 kb to 3 Mb, and 67% were deletions. However, genic CNVs, which represented 53% of all CNVs, were more frequently duplications (65%). Genic CNVs integrated between 1 and 17 genes, and included genes implicated in ASD etiology like NRXN1 and CHD2, as well as novel genes. CNVs were mainly inherited, with only 10% de novo.
We further evaluated the presence of autistic traits in parents, using appropriate questionnaires, and the type of inheritance of the CNV (inherited vs de novo). We observed a significant excess of autistic traits in the fathers that transmitted CNVs, mainly for the "aloof" personality, defined as lakking interest in social interaction. Analysis of familial correlation data from parents and probands showed a significant correlation between parents. We therefore show evidence for an excess of subthreshold autistic traits in CNV transmitting parents of children with ASD, particularly for paternal transmission. We also observed a tendency for assortative mating in families of affected individuals, in particular for inherited CNVs.
We conclude that a large fraction of CNVs are inherited and correlate with autistic traits in parents in the studied sample.

P06.07
Missing heritability of Korean patient with autism spectrum disorder(ASD)

J. E. Park[1], *S. A. Kim*[2], *M. Park*[3], *I. H. Cho*[4], *H. J. Yoo*[5];
[1]*Department of Psychiatry, Seoul National University Bundang Hospital and Department of Agricultural Biotechnology , College of Agricaltural Life Science, Seoul National University, Seoungnam-si, Korea, Republic of,* [2]*Department of Pharmacology, College of Medicine, Eulji University, Daejeon, Korea, Republic of,* [3]*Department of Preventive Medicine, College of Medicine, Eulji University, Seoungnam-si, Korea, Republic of,* [4]*Department of Psychiatry, Gacheon University School of Medical Science, Incheon, Korea, Republic of,* [5]*Department of Psychiatry, College of Medicine, Seoul National University Seoul National University Bundang Hospital, Seoungnam-si, Korea, Republic of.*

Genome-wide association studies (GWAS) have been identified SNPs associated with complex traits. However, a great deal of the heritable variation associated with common traits remains unaccounted for within the genome. The objective of this study is to discover large parts of additive genetic variance not typically associated with autism spectrum disorder (ASD) through GWAS in Korean population and estimates of ASD heritability.
Subjects with ASD were recruited through the Korean Autism Genetic Study Consortium. Each child was diagnosed as ASD by using the Korean versions of ADOS and ADI-R (Lord et al. 1994; Lord et al. 1997).
Total 146 patients were genotyped on the Affymetrix 5.0 platform. Genotype data for n=858 sex-matched controls were drawn from the Korea Association Resource database. Genotype data were filtered for <5% missingness/sample or /SNP; MAF >0.01; HWE p>0.0001. Cases were verified as unrelated using identity-by-descent estimation in PLINK v1.07. In order to examine the missing heritability in ASD, we applied genome-wide complex trait analysis (GCTA) to 142 case and 842 controls after data filtering.
The results identified phenotypic variants of 84.5% (±0.313 SE) with affected status of ASD, 7.0% (±0.027 SE) with topGWAS SNPs (± 1mb region) and 81.0%(± 0.313 SE) with nonGWAS SNPs. Increase from the genetic variance identified by top GWAS hits region indicates there might be more risk loci to be identified. Our results suggest that many common variants of small effect remain to be discovered, although GWAS is useful in identifying the most common variants associated with ASD.

Autism spectrum disorder (ASD) is a severe neurodevelopmental disorder with highly complex genetic predisposition.
Rare copy number variants (CNVs) are known to play a role in the genetic etiology of ASD. The follow-up of these rare events, by targeted gene sequencing and functional studies, has proven to be a powerful tool for the identi-

fication of novel candidate genetic loci.
In a genome wide CNVs screening performed by the AGP, a rare inherited microdeletion, disrupting two genes transcribed in the same direction, KLHL23 and SSB, was identified in an Italian ASD individual. This deletion, potentially resulting in a gene-fusion transcript, causes a frameshift with the introduction of a premature stop codon. No fusion transcript was detected by RT-PCR, suggesting that it is subject to "nonsense-mediated mRNA decay". KLHL23 encodes for a brain expressed Kelch-repeat protein of unknown function. While several CNVs affecting SSB are reported in controls making it an unikely dosege-sensitive gene, no CNVs have been previously described in KLHL23. KLHL23 expression analysis in peripheral blood of the CNV carriers did not show reduction of RNA levels, although we can't exclude that the deletion could have an effect on the brain.
In a mutation screening of KLHL23 in 85 multiplex familis with ASD we identified a damaging variant (M65V), absent in controls, and segregating with the ASD in an affected sibling pair.
Taken together our results suggest that rare variants altering KLHL23 function in the brain, could contribute to ASD risk in a small number of cases.

P06.09
Identification of MicroRNA -486-3p and miR-361-5p molecular signatures associated with autism in whole blood samples as a promising candidate biomarkers

N. Popov[1], *T. Vachev*[2,1], *V. Krasteva*[1];
[1]*Medical University of Plovdiv, Plovdiv, Bulgaria,* [2]*University of Plovdiv „Paisii Hilendarski", Plovdiv, Bulgaria.*

For molecular diagnostic purposes, it would be desirable to develop peripheral blood-based biomarkers which effectively identify disease state. As autism is one of the most debilitating neurocognitive disorders and only clinical criteria are available, some more effective and not so subjective signs are needed. To verify that pooled miRNA expression, reproduce the average of single subject values, we chose 3 micro RNAs (mir-766-3p, mir-486-3p and mir-361-5p), that were found to be dysregulated in autism patients whole blood in previous our work. Concordance between pooled and single subject results were demonstrated for 2 of the selected miRNAs by qRT-PCR analyses, identifying significant difference only for down-regulated mir-361 -5p (p<0,0001; mean RQ: - 0,38) and up-regulated mir-486-3p (p<0,0001; mean RQ: 8,003), but not for miR-766-3p (p=0,995) in autistic group. The expression changes of the miRNA signature were then evaluated for their correlation with the patients' clinical symptoms measured by Gilliam Autism Rating Scale (GARS) which reveals correlation of the communication and stereotype subscales with mir-361-5p (p=0,028/ p=0,043). The results indicated that the whole blood-based miRNA profiling is a promising way to identify candidate biomarkers for autism, and the identified miRNA signature warrants further investigation. Further molecular analysis on miRNA gene expression changes will give a more detailed picture about the miRNA associated mechanism in autism.

P06.10
Undestending MicroRNA gene expression signiture in peripheral blood of children with autism

T. Vachev[1], *V. Stoyanova*[2], *I. Minkov*[3], *N. Popov*[2];
[1]*University of Plovdiv, Plovdiv, Bulgaria,* [2]*Medical University of Plovdiv, Plovdiv, Bulgaria,* [3]*University of Plovdiv „Paisii Hilendarski", Plovdiv, Bulgaria.*

MicroRNAs are a class of sophisticated regulators of gene expression, acting as post-transcriptional negative regulators of gene expression that recognize their target mRNAs molecules through complementary base pairing. Due to the dynamic nature of the whole blood transcriptome, understanding miRNAs expression profile by examining mature miRNA signature in autism is a promising tool for discovery of novel disease-related biomarkers. To perform large-scale miRNA profiling we employed a pooled-RNA technique of 30 autistic patients' and 25 healthy controls' whole blood. Using µParafloTM miRNA microarray assay based on the Sanger miRBase v18.0 database, we found a set of 77 differentially expressed miRNAs (p<0,05) including miR-766-3p, log2 -1,10; miR-128, log2 - 0,97; miR-29a-3p, log2 0,67; miR-361-5p, log2 -0,70; miR-148a-3p, log2 0,96; miR-663, log2 -0,10; miR-486-3p, log2 -1,14. To validate the results of the microRNA microarray assay, we examined the expression of these miRNAs, by stem-loop qRT-PCR using pooled assay. All tested miRNAs showed a significant changes in accordance with microarray data (p<0,01), but miR-486-3p.
Finally, to study the modulation in protein-coding gene expression that may be associated with specific miRNAs changes, target studies were carried out using publically available database, miRWalk (http://mirwalk.uni-hd.de). We identified some genes connected with neuronal development as RELN and PTEN, other involved in epigenetic processes: DNMT and DICER, as downstream targets of the dysregulated miRNAs. All these findings clearly support the integrative genomic hypothesis of heterogeneous neurodevelopmental disorder, where specific changes in gene function contribute to disease phenotype.

P06.11
Runs of homozygosity associated with speech delay in autism in a Taiwanese Han population

P. Lin[1,2], *P. Kuo*[3], *S. S. Gau*[2,3,4];
[1]*Cincinnati Children's Hospital Medical Center, Cincinnati, OH, United States,* [2]*National Taiwan University Hospital, Taipei, Taiwan,* [3]*National Taiwan University College of Public Health, Taipei, Taiwan,* [4]*National Taiwan University College of Medicine, Taipei, Taiwan.*

Background: Runs of homozygosity (ROH) may play a role in schizophrenia and Alzheimer disease. Here, we aimed to test if ROHs are linked to autism.
Methods: A total of 315 Han Chinese affected with autism and 1,115 controls were genotyped with the Affymetrix SNP 6.0 array. ROH was defined as an extended homozygous haplotype spanning at least 500 kb. We also used Affymetrix GeneChip HG U133_Plus 2.0 to perform gene expression analysis.
Results: The case-control analysis yielded no genome-wide significant associations. An ROH region on 11q22.3 was significantly associated with speech delay (p = 2.51 x 10^{-11}). Among these genes, NPAT (nuclear protein, ataxia-telangiectasia locus) and ATM (ataxia-telangiectasia mutated) are linked to ataxia telangiectasia characterized by language impairment; CUL5 (culin 5) may regulate neuronal migration to influence cortical layering associated with language development. Our gene expression analysis also show that the NPAT gene was less expressed in cases with language impairment than cases without language impairment (p = 5.67 x 10^{-10}). We further obtained nominal evidence for the association between speech delay and an ROH region on 11q22.3 in another independent sample of 1,387 subjects (p = 0.037). The ROH on 11q22.3 remained to be significantly associated with speech delay in combined samples (Stouffer's z trend = 0.0005).
Conclusions: Our findings suggest that extended recessive loci on 11q22.3 may play a larger role in in language impairment than susceptibility to autism. More research is warranted to investigate if these genes, especially NPAT, influence speech pathology by perturbing cerebellar functions.

Autism Spectrum Disorders (ASD) are characterized by deficits in social interaction, communication, and repetitive behaviour. Recent studies have highlighted the involvement of rare copy-number variations in the genetic etiology of ASD particularly those affecting genes involved in the neuronal synaptic complex. Among them, the SHANK gene family consists of three members: SHANK1, SHANK2 and SHANK3, which encode scaffolding proteins required for formation and function of neuronal synapses. SHANK2 mutations have been associated with ASD and mild intellectual disability. Recently, three patients with autism carrying a de novo deletion of SHANK2 associated with a duplication of the alpha 7 nicotinic receptor CHRNA7 were reported. Based on these observations, a „multiple hit model" for ASD has been proposed for SHANK2.
Here we reported a patient with autism, minor dysmorphic features, hypotony, and multiple ear infections. The whole genome SNP array (HumanCytoSNP-12, Illumina) analysis revealed a de novo 11q13.3q13.4 deletion (69,789,180-71,783,240) of 1.9 Mb encompassing 6 referenced OMIM genes including SHANK2. In addition, the patient carried an intermediate CGG re-

peat length at the Fragile X mental retardation (FMR1) locus inherited from his mother.
We discuss the genotype-phenotype correlation of the 11q13.3 deletion and the co-occurrence of the 11q13.3 deletion and the FRAXA intermediate allele.

A plethora of data on germ-line genomic rearrangements in brain disorders including autism and schizophrenia does exist. On the other hand, the contribution of non-heritable genomic alterations to the pathogenesis is hardly appreciated. Here, we have assessed post-zygotic autosomal aneuploidy in prefrontal cortex of the diseased and normal brain by molecular cytogenetic techniques (FISH and interphase chromosome-specific multicolor banding with DNA probes for chromosomes 1, 7, 8, 9, 10, 11, 16, 17 and 18). Twelve autistic, 19 schizophrenic and 27 control samples provided by the Brain and Tissue Bank for Developmental disorders, University of Maryland and bank of our institute were analyzed. Aneuploidy rate per autosome was 0.3-0.8% in all three cohorts analyzed (0.46%, 0.62% and 0.59%). However, we observed statistically significant increase of chromosome 9 aneuploidy in the autistic brain. In schizophrenia, chromosome 1 and 18 aneuploidy rates were significantly increased. Additionally, we performed array CGH and in silico analysis of our data on genomic rearrangements in childhood neurodevelopmental diseases (124 individuals) and found that CNV burdens in these individuals typically affect two pathways specific for brain cells: cell cycle regulation and programmed cell death. We concluded that somatic genome variation (chromosome-specific mosaic aneuploidy) is a non-heritable genetic factor contributing to pathogenesis of brain disorders, that is, however, a result of specific CNV burdens. Our data provide a basis for a new (mitotic) theory of neuropsychiatric diseases. Supported by the President of the Russian Federation Grant MD-4401.2013.7 and RFBR 12-04-00215-a.

P06.14

Microdeletion in the 4p16.3 region in a case of autism

*P. Dello Russo, M. Robazza, E. Demori, L. Bortotto, D. Romagno, N. Passon, G. Crichiutti, A. Pusiol, A. Rosolen, **G. Damante**;*
Azienda Ospedaliro-Universitaria S. Maria della Misericordia, Udine, Italy.

A large body of evidence suggests that autism is a multifactorial disease with a strong genetic component; however the underlying mechanisms are not yet clear. We report a patient with a normal development up to the third year of life. At this age the child presented impairment of reciprocal social interaction, deficit in verbal communication ability, stereotyped behavior with head banging, brief attention span, poor eye contact. The diagnosis of autism was done according to the "Autism diagnostic Observation Scale". Actually the child is 10 years old. Brain NMR and vision are normal. Electroencephalogram shows spike/wave complexes at 2-3Hz over the right frontal region. Conventional karyotype is 46, XY. Array-based comparative genomic hybridization (aCGH) reveals a 647 Kb microdeletion of 4p16.3. The microdeletion found in our analysis is closed to but does not include the critical region associated with the Wolf-Hirschorn syndrome (WHS); accordingly, the child exhibited mild dysmorphic features, which included a prominent forehead and glabella, but not the typical WHS appearance. Evaluation of both parents demonstrates that the microdeletion of the child is a "de novo" mutation. Only limited number of coding genes (namely ZNF595, ZNF718, PDE6B, ZNF732, ZNF141, ZNF721, PIGG, MYL5) are located in the deleted chromosomal area. Since a different patient with autism and a similar microdeletion in the 4p16.3 region has been recently described (Velinov et al., Annual Meeting of American Society of Human Genetics, 2008), we hypothesize that such genome alteration might be associated with the autism spectrum disorders.

Copy Number Variants (CNVs) play an important role in susceptibility to ASD, often mediated by the deletion or duplication of genes involved in synaptic structure and function. In this study we tested the hypothesis that there is an enrichment in CNVs encompassing synaptic transmission genes in ASD.
To obtain a list of genes involved in synaptic structure and function, we query pathway databases for synaptic pathways (KEGG and GO). By intersecting this list with the results of a large CNV genomic screening in ASD patients (performed by the Autism Genome Project), and CNV information on the Database of Genomic Variants (DGV), we found a significantly increased burden of CNVs encompassing synaptic genes in ASD subjects compared to DGV controls (Fisher exact test P=2.2X10^{-16}, OR=1.47).
Detailed analysis of the frequencies of each synaptic gene duplicated or deleted by CNVs in ASD and control subjects identified 39 genes that were significantly more frequent in ASD (P<0.05). Closer inspection of CNV overlap between the ASD sample and additional control databases (*eg* SAGE, PopGene) highlighted synaptic structure or function genes (eg *NF1*, *GABRG1*, *CHRNA7*) that warrant further investigation. Additionally, 5 synaptic genes, *PLA2G1B, PPP2R3C, KCNK7, ADCY7* and *RAPSN*, were disrupted by CNVs exclusively in the ASD dataset, and were also absent from the additional control CNV databases queried.
The present results show an excess of structural alterations encompassing synaptic genes in ASD and highlight candidate genes for sequencing and functional studies.

P06.16

A *NCAM2* deletion in a patient with autism

***C. Scholz**[1], D. Steinemann[2], M. Arslan-Kirchner[1], M. Stuhrmann[1], M. Roy[3], J. Schmidtke[1];*
[1]Institute of Human Genetics, Hannover Medical School, Hannover, Germany, [2]Institute for Cellular and Molecular Pathology, Hannover Medical School, Hannover, Germany, [3]Psychiatric Clinic, Hannover Medical School, Hannover, Germany.

An 8-year-old boy with autism spectrum disorder, speech delay, behavioural problems, disturbed sleep and macrocephaly presented in our genetics clinic. He is the first child of non-consanguineous parents. Chromosomal analysis had revealed a normal male karyotype 46,XY, and testing for fragile X syndrome and *PTEN* sequencing was inconspicuous.
Array-CGH analysis showed a microdeletion of 1.6Mb: arr 21q21.1-q21.2(22444986-24047363)x1. This part of the chromosome contains the entire *NCAM2* gene and no other functional genes. His mother also carries this microdeletion. She has no obvious behavioural features of autism, but also is macrocephalic. Three maternal blood relatives are reported to have speech problems. Results of psychological assessments of the mother and the other affected individuals are pending.
Autism spectrum disorder (ASD, OMIM 209850) encompasses different forms of autism with a broader phenotype. Two-thirds of all patients with ASD suffer from mental retardation. Among the genes involved, *NCAM2* has been assumed to play a role in the development of ASD because of its function in neurites (outgrowth, bundling). In the literature, there is one report of an autistic boy with an 8.8 MB-microdeletion involving 19 genes including *NCAM2* and another autism-related candidate gene, *GRIK1*. Our case supports the assumption that *NCAM2* deficiency, as other cell adhesion pro-

tein defects, plays a role in the development of autism, speech development and macrocephaly, perhaps with variable expressivity.

Autism spectrum disorder (ASD) is an early childhood neurodevelopmental disorder characterized by a significant genetic aetiology and a prevalence currently estimated at 1/100. Epidemiological studies described that ASDs are heterogeneous at both clinical and genetic levels, which has been further illustrated by the large number of loci and genes that have been identified to date (>100). Several biological pathways have been highlighted, particularly the NMDA receptor multiprotein (NRC) complex, affected by copy number variations (CNV) and mutations enriched in NRC proteins encoding genes.
We performed a global genetic study of 100 French families including at least 1 individual with ASD, which was included in the research project "Neurophysiological Molecular and Developmental Analysis of the Glutamate Synapse in Autism (NMDA-Autism)" (ClinicalTrials.gov NCT01770548).
For each family, we firstly performed a high-resolution pangenomic comparative genomic hybridization (CGH) analysis with 1M CGH Agilent Array format to identify rare or de novo CNVs; Secondly, a high-throughput targeted sequencing of 216 genes mostly belonging to the NRC complex was carried out with the SureSelect Agilent strategy in order to assess the contribution of gene mutations in our cohort.
Preliminary results on CGH experiments led us to identify small rare CNVs in several known regions (20p12.1 MACROD2; 18q21.1 KATNAL2; 11p13.11) or novel potential candidates such as FRMPD4, GUCY2F and NXPH3. We have also observed several large genomics variations previously described (1,2Mb amplification at 16p13.11 and 5,6 Mb deletion at 11q14.2-q14.3). The results from the high-throughput sequencing analysis, which is currently being performed, will be also presented.

Autism spectrum disorders (ASDs) are highly heritable, neurodevelopmental conditions, showing extreme genetic heterogeneity. While it is well established that de novo genetic variation plays an important role in ASD risk, recent studies have demonstrated a convincing evidence of a rare recessive contribution to the heritability of ASDs.
In the genome-wide CNV study carried out by the Autism Genetic Consortium (AGP), we identified one homozygous deletion intersecting the CTNNA3 gene in an Italian proband with ASD and moderate intellectual disability (PIQ=50). This deletion includes a coding exon, leading to a putative frameshift and premature stop codon, inherited from both parents, each heterozygote for a deletion of slightly different length. The unaffected sister is also heterozygote for the deletion.
CTNNA3 encodes for the alfaT-catenin protein that has a crucial role in cellular adherence showing suggestive association in GWAS and a de novo deletion.
Even if the frequency of exonic deletions of CTNNA3 is not significantly different between ASDs cases and controls (17/2446 cases and 35/5097 controls, P=.88), no homozygous exonic deletions were found in a sample of 5097 controls, suggesting that only the complete knockout of CTNNA3 could cause or confer susceptibility for ASDs. Expression analysis of alfaT-catenin and alfaN-catenin proteins in mouse cortex and hippocampus (P0-P90), provided further support of a role of CTNNA3 in early mid-fetal development of the brain.
While the exact biological significance of CTNNA3 homozygous deletion is yet to be determined, we hypothesize that it could have clinical relevance to the ASDs phenotype in this Italian patient.

Copy number variants (CNVs) have repeatedly been found to cause or predispose to Autism Spectrum Disorders (ASDs). For diagnostic purposes, we screened 194 patients with ASDs for CNVs using Illumina SNP arrays. In several patients, we also analyzed candidate genes located in inherited deletions to unmask autosomal recessive variants. Three CNVs, a *de novo* triplication of chromosome 15q11-q12 of paternal origin, a deletion on chromosome 9p24 and a *de novo* 3q29 deletion, were identified as the cause of the disorder in one patient each. We also identified multiple private or recurrent CNVs, the majority of which were inherited from asymptomatic parents. Finally, an autosomal recessive cause was considered in two patients: a homozygous 1p31.1 deletion encompassing *PTGER3* was identified in a patient and a rare missense variant in *DOCK10* was found in a second patient in association with an inherited deletion that deleted the entire gene. Although highly penetrant CNVs or variants inherited in an autosomal recessive fashion were detected in rare cases, our results mainly support the hypothesis that CNVs contribute to ASDs in association with other CNVs or point variants located elsewhere in the genome. Identification of these genetic interactions in individuals with ASDs constitutes a formidable challenge.

P06.20

0.12Mb microdeletion at 19p13.2 including NFIX in an individual with autism spectrum disorder.

I. Ohashi[1], *Y. Kuroda*[1], *T. Naruto*[1], *K. Ida*[1], *K. Enomoto*[1], *K. Tanoue*[2], *K. Kurosawa*[1];

[1]*Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan,* [2]*Division of Integrated Pediatrics, Kanagawa Children's Medical Center, Yokohama, Japan.*

Marshall-Smith syndrome (MSS) is the overgrowth syndrome, characterized by tall stature, macrocephaly, distinctive facial appearance, and intellectual disability. Recently, Sotos-like and MSS were found to be caused by mutations of Nuclear factor I-X (NFIX). We describe an additional male patient with microdeletion at 19p13.2 encompassing NFIX. He was born to nonconsanguineous parents at 40 weeks of gestation. His birth weight was 2570 g, and height 46 cm. At the age of 2 years and 8 months, he was referred to our clinic for a diagnostic evaluation because of developmental delay and growth retardation. His weight was 10.6 kg (-1.8 S.D.), height 86.7 cm (-1.2 S.D.), and OFC 48.0 cm (-0.7 S.D.). He could crawl, but could not walk alone and speak a significant word. He had some autistic traits and stereotypes.He was

medicated with antiepileptics for recurrent febrile convulsions. Array CGH revealed 0.12 Mb deletion at 19p13.2 encompassing NFIX. Further analysis with quantitative PCR confirmed the deletion of NFIX as a de novo event. Our patient had a relative macrocephaly, but did not present overgrowth and characteristic facial features as MSS. The autistic traits are the most prominent clinical feature in our patient. Haploinsufficiency and mutations in the DNA-binding /dimerization domain of NFIX causes Sotos-like syndrome, whereas the truncated mutations of NFIX represent MSS [Malon et al., 2010; Yoneda et al., 2012; Priolo et al., 2012]. The present report provides insight into consideration of genotype-phenotype correlation in NFIX mutations.

Analysis of the hexonucleotide repeat expansion and founder haplotype at C9ORF72 in an Irish psychosis case-control sample.

C. A. Fahey;
TCD, Dublin, Ireland.

A hexonucleotide repeat expansion 'GGGGCC' in an intronic region of the C9ORF72 gene has been found to account for up to 70% of amyotrophic lateral sclerosis (ALS), and this locus also being implicated in the pathogenesis of frontotemporal dementia (FTD). Study of an independent FTD sample showed a strong association between C9ORF72 mutations and psychotic symptoms. We sought to screen a large Irish psychosis case-control sample for evidence of association between the repeat expansion and psychosis. We carried out haplotype analysis on this region, due to reports of a founder haplotype. Our sample included 1,165 cases and 1,283 controls. We used a reverse-primed PCR method to amplify the hexonucleotide repeat expansion. Haplotype analysis was carried out using available GWAS data for these samples. The distribution of repeat numbers was very similar for cases and controls. We identified four samples that carried a repeat number approaching the pathogenic range >30. There were two controls samples (26 and 25 repeats respectively) and two schizophrenia cases (27 and 28 repeats). Haplotype analysis found that for the 512 samples that carried more than 7 repeats, 482 (94%) carried the founder haplotype. The significance of the intermediate number of repeats (between 24 and 29) is still unclear. Haplotype analysis showed a clear association between repeat number and the founder haplotype. It would appear that this haplotype is not unique to ALS-FTD cases, but its presence predisposes this region to the repeat expansion, and in turn this may lead to a greater risk of molecular instability.

University of Granada, Granada, Spain, [4]Group of Neurodevelopment and Psychosis. Institute of Biomedicine of Seville (IBIS). Virgen del Rocío University Hospital, Sevilla, Spain.

Objective: To determine if the age at onset of cocaine use affects the manifestation of psychotic symptoms and if there are differences on the age at onset of cocaine use that are dependent on the expressed polymorphism of the Catecol-O-Metil Transferase (COMT).
Methodology: The sample consists of 138 cocaine users. In order to evaluate the presence of psychotic symptoms we used the Community Assessment Psychic Experience (C.A.P.E.) test. This test evaluates the expression of both positive (paranoia, deliriums, hallucinations…) and negative (lack of social and emotional skills…) symptoms, and the associated discomfort.
Results: The results show differences among the cocaine users in the expression of psychotic symptoms, depending on age. The individuals that started using cocaine when they were 17 or younger scored higher in expression of positive psychotic symptoms (p=0.078) and associated discomfort (0.047) when compared with individuals that started using cocaine when they were 18 or older. In addition we have found significant differences in the age at onset of cocaine use associated to the expressed COMT polymorphism. Cocaine users with Met-Met polymorphism had an earlier age at onset (17.5 DT=2.6) than those with Val-Val (18.1 DT=2.1) o Met-Val (19.5 DT=3.7) polymorphisms.

Opioids, such as morphine and fentanyl, are widely used as effective analgesics for the treatment of acute and chronic pain. In addition, the opioid system has a key role in the rewarding effects of morphine, ethanol, cocaine and various other drugs. Although opioid sensitivity is well known to vary widely among individual subjects, several candidate genetic polymorphisms reported so far are insufficient for fully understanding the wide range of interindividual differences in human opioid sensitivity. By conducting a multistage genome-wide association study (GWAS) in healthy subjects, we found that genetic polymorphisms within a linkage disequilibrium block that spans 2q33.3-2q34 were strongly associated with the requirements for postoperative opioid analgesics after painful cosmetic surgery. The C allele of the best candidate single-nucleotide polymorphism (SNP), rs2952768, was associated with more analgesic requirements, and consistent results were obtained in patients who underwent abdominal surgery. In addition, carriers of the C allele in this SNP exhibited less vulnerability to severe drug dependence in patients with methamphetamine dependence, alcohol dependence, and eating disorders and a lower 'Reward Dependence' score on a personality questionnaire in healthy subjects. Furthermore, the C/C genotype of this SNP was significantly associated with the elevated expression of a neighboring gene, *CREB1*. These results show that SNPs in this locus are the most potent genetic factors associated with human opioid sensitivity known to date, affecting both the efficacy of opioid analgesics and liability to severe substance dependence. Our findings provide valuable information for the personalized treatment of pain and drug dependence.

Genetics of the development of heroin addiction and the pharmacogenetics of the substitution therapy

A. Vereczkei[1], *Z. Demetrovics[2], A. Szekely[2], P. Sarkozy[3], P. Antal[3], A. Szilagyi[4], M. Sasvari-Szekely[1], C. Barta[1];*
[1]Department of Medical Chemistry, Molecular Biology and Pathobiochemistry, Semmelweis University, Budapest, Hungary, [2]Institute of Psychology Eötvös Loránd University, Budapest, Hungary, [3]Technical University of Budapest, Measurement and Information Systems, Budapest, Hungary, [4]3rd Department of Internal Medicine, Research Laboratory, Semmelweis University, Budapest, Hungary.

Primary goal of this study was to clear the role of the dopaminerg genes in the pathophysiology of heroin addiction and also expanding the research, using modern molecular biology technics in order to investigate gene variants in the shared genetics of common addicitons.
In addition to our case-control study, we carried out a TaqMan® OpenArray® study on *in silico* selected addiction candidate genes. Investigated

polymorphisms of the case-control study were: the dopamine D4 receptor gene (DRD4) III.exon VNTR; rs1800955, rs747302, rs936462 polymorphisms and the 120bp duplication; the dopamin trasporter 3' and VIII.intron VNTRs; rs1800497 of the ANKK1 and rs1079597, rs1800498 of the dopamine D2 gene (DRD2). Further goal was to determine environmental and genetic factors effecting the efficiency of the substitution therapy of heroin dependence. Previously in our lab two polymorphisms of the dopamine D4 receptor gene showed association with the therapeutic response of methadone-treated patients.
The results of the case-control study showed significant association between the ANKK1 rs1800497 (p=0.009), the DRD2 rs1079597 (p=0.003) and the DRD4 rs1800955 (p=0.007) and heroin dependence. Additional bioinformatic analyses revealed an indirect effect of the DRD4 rs936462 (p=0.0013). The OpenArray analysis found 5 nominally significant associations, from which only one SNP in the ALDH2 gene (aldehyde dehydrogenase 2) stayed significant after multiple correction. ALDH2 is thought to be involved in the metabolism of dopamine so probably has a role in the pathophysiology of other addictions. This study reinforces the results of a previous Chinese association study between the ALDH2 and heroin dependence.

Expression of neurotransmitter regulatory and neurodevelopment genes in peripheral blood of patients at the first episode of psychosis

V. K. Ota[1], *C. S. Noto*[1], *A. Gadelha*[1], *M. L. Santoro*[1], *P. N. Silva*[1], *J. J. Mari*[1], *M. I. Melaragno*[1], *M. A. C. Smith*[1], *Q. Cordeiro*[2], *R. A. Bressan*[1], *S. I. Belangero*[1];
[1]*UNIFESP, Sao Paulo, Brazil,* [2]*ISCMSP, Sao Paulo, Brazil.*

Schizophrenia is a severe mental health disorder with a high heritability. The study of gene expression levels in blood of patients in the beginning of the disease, such as first-episode of psychosis (FEP) may be useful to detect changes in gene expression despite treatment effects. In this study we aimed to compare the expression levels of genes related to neurotransmission and neurodevelopment, in blood of FEP patients (*N*=30) and healthy controls (*N*=29). Whole blood was collected from each participant during clinical assessments. Expression levels of 40 genes related to neurotransmission and neurodevelopment were quantified with a customized RT^2 Profiler™ PCR Array, which is based on SYBR Green detection of cDNA amplification. For data analysis, we compared $2^{-\Delta Ct}$ values of FEP patients and healthy controls using t-test. Twenty-eight of 40 genes presented undetectable expression levels in whole blood and, hence were excluded from the analyses. Significant downregulation of two genes was observed: *GCH1* (Fold regulation (FR)= -1.32, *p*=0.005); and *TACR2* (FR= -1.32, *p*=0.017). *GCH1* codes for GTP cyclohydrolase I, an enzyme involved in the synthesis of BH4, which is an essential cofactor for tyrosine, serotonin and L-Dopa. Moreover, it was previously suggested as a candidate gene in a linkage analysis in bipolar disorder. Although no study had investigated *TACR2* gene (Tachykinin receptor 2) in psychosis, its antagonists exhibited anti-depressant-like activity. Therefore, both genes seem to have a role in the genesis of psychosis leading towards a better understanding of illness. Funding for this study was provided by FAPESP 2010/08968-6 and 2011/50740-5.

[1]*Max Planck Institute of Psychiatry, Munich, Germany,* [2]*Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany,* [3]*Laboratory of NeuroGenetics, Department of Psychology and Neuroscience, Duke University, Durham, NC, United States.*

Exposure to adverse life events, which is associated with an activation of the stress hormone system, is an important risk factor for the development of major depressive disorder (MDD). A main effector of this system is the glucocorticoid receptor (GR), a nuclear receptor that functions as a transcription factor. We characterize genetic variants that moderate short-term effects of GR activation on mRNA transcription in peripheral blood cells. We demonstrate that these functional variants are significantly enriched among variants associated with MDD in a large case-control study and interact with early adversity to predict amygdala reactivity to threat. The transcripts regulated by these functional MDD risk variants in human blood are also regulated by GR activation and chronic adolescent stress in mouse brain and point to ubiquitination and proteasome degradation and their impact on neurite outgrowth as important stress-sensitive systems influencing the risk to suffer from MDD.

P06.27

Upregulation of GCHFR gene expression in peripheral blood of first episode psychosis patients before and after antipsychotic treatment

M. L. Santoro, *V. K. Ota, C. S. Noto, A. Gadelha, P. N. Silva, J. J. Mari, M. I. Melaragno, M. A. C. Smith, Q. Cordeiro, R. A. Bressan, S. I. Belangero;*
UNIFESP, São Paulo, Brazil.

Schizophrenia is a severe mental health disorder with a high heritability. The study of gene expression levels in peripheral blood, screening exclusively drug-naïve patients at two time points, may be useful to detect changes across disease progression and treatment. In this study we aimed to compare the expression levels of neurotransmission genes in peripheral blood of 30 drug-naïve first episode psychosis patients (FEP) before and after antipsychotic treatment with risperidone. All patients were evaluated by a psychiatrist twice (at admission and 8 weeks after treatment). Expression levels of 40 genes were quantified with a customized PCR Array which is based on SYBR Green detection of cDNA amplification. We compared 2-ΔCt values of FEP patients before and after treatment using paired T-test, considering p<0.05. GTPcyclohydrolase I feedback regulator gene (GCHFR) was significantly upregulated in FEP patients after risperidone treatment (p=0.025). GCHFR is an important modulator of GTPcyclohydrolase I (GCH1), their interaction influence directly the synthesis of tetrahydrobiopterin (BH4), which is a vital cofactor maintaining availability of some monoamine neurotransmitters. These data agree with other study in literature that described a deficiency of BH4 in patients compared to controls. Interestingly, in another study of our group that investigated the same FEP individuals, we found a downregulation in GCH1 gene compared to healthy controls. In this way, we suggest this upregulation of GCHFR after treatment could be related to risperidone effectiveness, by altering BH4 synthesis. Our study may contribute to a better understand the BH4 and GTPcyclohydroxylase system in psychosis and antipsychotic treatment.

P06.28

A *de novo* 16p11.2 microdeletion encompassing *SRCAP* gene identified by array-CGH in a patient with Floating-Harbor syndrome.

F. Gerundino[1], *C. Giachini*[1], *C. Antonelli*[2], *B. Federighi*[2], *G. Marseglia*[1], *C. Pescucci*[1], *M. Benelli*[1], *F. Torricelli*[1];
[1]*Genetic Diagnostic Unit, Careggi University Hospital, Florence, Italy,* [2]*Neurologic and Psychiatric Department, University of Florence, Florence, Italy.*

We describe a patient referred to our diagnostic centre for speech delay, global developmental delay and behavioural problems with normal standard karyotype, as indications for array-CGH analysis.
Molecular karyotyping revealed a 186 kb *de novo* microdeletion in 16p11.2 that encompasses 9 RefSeq genes including *SRCAP* gene (Snf2-related CREBBP activator protein, MIM #611421).
Recently, mutations in the *SRCAP* gene have been shown to cause Floating-Harbor syndrome (FHS, MIM#136140), a rare disorder characterized by peculiar facial features, short stature with delayed osseous maturation and speech impairment. To date, 19 out of 22 patients with clinical diagnosis of FHS and heterozygous truncating mutations in the final exon (34th) of *SRCAP* have been reported. The absence of mutations in 3 patients suggests the genetic heterogeneity of the syndrome. After the arrayCGH result, a new clinical evaluation was performed to evaluate the possibility of clinical overlapping between our patient and reported patients with a clinical and molecular diagnosis of FHS. On the basis of this second examination, it appears evident that the patient fulfils the diagnostic criteria for FHS. This is the first report of an heterozygous deletion of *SRCAP* gene indicating that in addition to truncating mutations reported so far partial or whole-gene deletion may be present. Therefore, it could be suggested to perform copy number analy-

sis in patients whose clinical examination is strongly suggestive of FHS and which are negative for point mutations in the final exon of *SRCAP.*

P06.29

Genetic syndromes are frequently found in patients manifesting with primary neuropsychiatric disorders and developmental co-morbidities

J. So[1,2,3], *H. Faghfoury*[2], *J. Silver*[2], *T. Gofine*[3], *J. L. Kennedy*[1];
[1]*Centre for Addiction and Mental Health, Toronto, ON, Canada,* [2]*Fred A. Litwin Family Centre for Genetic Medicine, University Health Network and Mount Sinai Hospital, Toronto, ON, Canada,* [3]*Ontario Shores Centre for Mental Health Sciences, Whitby, ON, Canada.*

Background: Many genetic syndromes present with psychiatric disorders. We aim to determine the role and prevalence of hidden genetic conditions in patients with psychiatric disorders and comorbidities. This has the potential to significantly impact the standard of care and treatment of selected individuals with psychiatric impairment. Methods: We prospectively recruit patients ≥16 years of age with psychiatric disorder(s) and at least one of 1) neurologic abnormality, 2) developmental delay (DD), autism spectrum disorder (ASD) or pervasive DD (PDD), 3) dysmorphic features, 4) congenital anomalies or 5) family history of DD, ASD or PDD. A clinical database of phenotypic correlates is being established to delineate the highest yield data that lead to the most effective and efficient diagnosis of genetic syndromes in patients with neuropsychiatric disorders. Results: Of the initial 62 patients recruited, 15 (24.2%) have been diagnosed with genetic conditions. This includes seven patients with six different single gene disorders, six patients with six distinct chromosomal variants and two patients with different metabolic disorders. Discussion: Our preliminary results have begun to demonstrate that genetic syndromes are common in patients with primary psychiatric disorders. Many of the genetic conditions identified in this cohort have implications for medical surveillance, management and, in some cases, treatment. The high diagnostic yield in patients with "psychiatric plus" phenotypes demonstrates the significance of psychiatric disorders in genetic syndromes and vice versa. Identifying phenotypic 'red flags' will enable development of algorithms to make important, possibly treatable, genetic diagnoses in psychiatric patients in a more efficient manner.

DNA methylation profiles of paediatric obsessive-compulsive disorder (OCD)

P. D. Arnold[1,2], *D. T. Butcher*[1], *J. L. Kennedy*[3,2], *G. L. Hanna*[4], *D. R. Rosenberg*[5], *R. Weksberg*[1,6];
[1]*Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada,* [2]*Department of Psychiatry and Institute of Medical Science, University of Toronto, Toronto, ON, Canada,* [3]*Centre for Addiction and Mental Health, Toronto, ON, Canada,* [4]*Department of Psychiatry, University of Michigan, Ann Arbor, MI, United States,* [5]*Department of Psychiatry and Behavioral Neuroscience, Wayne State University, Detroit, MI, United States,* [6]*Department of Paediatrics and Institute of Medical Science, University of Toronto, Toronto, ON, Canada.*

Obsessive-Compulsive disorder (OCD) is a complex, common and debilitating psychiatric disorder. Heritability estimates range from 40% to 65% suggesting that genetic factors play a role in the etiology of this disorder. However, there are other potential important determinants, including epigenetics. Epigenetic mechanisms, such as DNA methylation, have increasingly been shown to be important in the etiology of complex disorders. We hypothesized that there are alterations in DNA methylation patterns in children with OCD compared to controls. We used a novel genome-wide approach to identify epigenetic variants. Analysis of blood DNA methylation patterns in 10 OCD patients compared to 10 controls identified both gain and loss of methylation at a number of CpG sites. Candidate DNA methylation alterations identified in this initial investigation were highly relevant to the OCD phenotype and include altered DNA methylation in promoters of genes that function in glutamate signaling, myelin synthesis and lipid transport. We then obtained DNA methylation profiles using the Illumina Infinium Methylation450 array in an expanded cohort of 30 OCD patients compared to 30 tissue, age and sex-matched controls based on saliva collected using Oragene•Dx saliva kits (DNA Genotek). Data were analyzed using the IMA package in R and Genome Studio software from Illumina. The identification of epigenetic modifications in children with OCD will lead to an improved understanding of the pathophysiology and molecular mechanisms leading to this disorder. These epigenetic alterations could provide early diagnostic biomarkers for OCD which may influence treatment strategies, including both pharmacologic and cognitive behavioural therapy.

‚Association of *ADARB1* gene with major psychiatric disorders'

S. Djurica[1], *J. Miladinovic*[1], *M. Pantovic*[2], *M. Ivin*[1], *S. Svikovic*[1], *G. Brajuskovic*[1], *S. Romac*[1], *M. Ivkovic*[2], *D. Savic Pavicevic*[1];
[1]*University of Belgrade, Faculty of Biology, Centre for Human Molecular Genetics, Belgrade, Serbia,* [2]*Clinical Centre of Serbia, Institute of Psychiatry, Belgrade, Serbia.*

Adenosine to inosine RNA editing, catalyzed by ADARs, is a major mechanism for transcriptome diversification in the nervous system with an important role in neurotransmission, neuronal outgrowth and plasticity. Changes in the editing of a few transcripts have been reported in postmortem studies on brains of individuals with psychiatric disorders, with the most consistent results obtained for suicide victims. Moreover, studies on mice suggest antipsychotics may reverse altered editing. To test hypothesis that variants in *ADAR* genes may contribute to these phenomena, we study association between *ADARB1* gene and major psychiatric disorders. A population based case-control study included 128 individuals with schizophrenia (SCZD), 140 with major depressive disorder (MDD) and 77 with bipolar disorder (BD), all diagnosed according to DSM-IV criteria, and 163 controls. Twelve tagSNPs in *ADARB1* gene were selected using HapMap database and HaploView. Genotyping was performed by TaqMan probes and data were analyzed by PLINK.
We show association of rs1051385 with SCZD (p=0.04, Pearson chi-square test). rs1051385 is located in the 3'UTR and may affect *ADARB1* expression. This may be consistent with previously reported increased expression of ADARB1 variants with reduced catalytic activity in SCZD. Furthermore, we show specific *ADARB1* haplotypes association with attempted suicide in MDD (p=0.0002, Pearson chi-square test) and SCZD (p=0.009, Pearson chi-square test) patients, and with SSRIs response in MDD patients (p=0.001, Pearson chi-square test). To our knowledge, this is the first study reporting association of *ADARB1* gene with psychiatric disorders, and it further underscores the importance of RNA editing in psychiatric pathology.

P06.32

Interrater reliability of hypernasality amongst psychiatrists

T. S. Eapen[1], *N. I. Erdmann*[2];
[1]*Montfort Hospital, Ottawa, ON, Canada,* [2]*none, Berlin, Germany.*

22q11.2 Deletion Syndrome is a significant risk factor for the development of psychiatric disorders. Although 22q11.2DS is commonly detected by other specialties in infancy, individuals are not screened if the anomalies do not warrant medical or surgical interventions. Facial dysmorphisms in 22q11.2DS are not clinically reliably detected. If hypernasality, found in ~90% of adult probands, is accurately and reliably detected by psychiatrists untrained in voice resonance abnormalities, it may increase the detection of 22q11.2DS. **Objective:** To determine if psychiatrists can accurately and reliably detect hypernasality. **Methods:** 40 adult psychiatrists from the Ottawa Hospital or the Royal Ottawa Mental Health Center listened to 20 voice samples (10 male, 10 female) repeated three times. Psychiatrists characterized each voice sample according to a 4-point Likert scale (1 = normal, 2 = mildly hypernasal, 3 = moderately hypernasal, 4 = very hypernasal). **Results:** Sensitivity and specificity of hypernasality detection (95% CI) were as follows: 88.5% (86-90) and 64.4% (61-67). Using logistic regression analysis, sensitivity and specificity were not affected by psychiatrist gender (p = 0.803; p = 0.520); native language (p = 0.637; p = 0.542); general vs. subspecialty psychiatry (p = 0.487; p = 0.550); gender of voice sample (p = 0.887; p = 0.416). Repeated exposure significantly affected the sensitivity (p = 0.003) of hypernasality detection but not specificity (p = 0.877). **Conclusions:** With no prior training, psychiatrists accurately and reliably detect hypernasal speech; detection of hypernasality is not affected by native language and

psychiatrist gender, voice sample gender, and psychiatric subspecialty.

P06.33
Duplications of RB1CC1 on 8q11.23 in neuropsychiatric disorders: presentation of a further patient.

K. Varvagiannis[1], *S. Gimelli*[2], *J. Fluss*[3], *S. Eliez*[4], *E. Stathaki*[2], *F. Sloan-Béna*[2], *S. E. Antonarakis*[1,2], *A. Bottani*[2];
[1]*University of Geneva, Geneva, Switzerland,* [2]*University Hospitals of Geneva, Geneva, Switzerland,* [3]*Geneva Children's Hospital, Geneva, Switzerland,* [4]*University of Geneva Medical School, Geneva, Switzerland.*

Duplications of RB1CC1 have been associated with various neurodevelopmental and psychiatric disorders such as psychomotor delay, epilepsy, autism spectrum disorder (ASD), and schizophrenia. A damaging de novo mutation in this gene has recently been identified in a schizophrenia patient. However, duplications of this locus have also been described in healthy individuals, thus complicating interpretation of such findings. Altogether, there is growing evidence suggesting a possibly incomplete penetrance as well as an important phenotypic variability of RB1CC1-associated disorders.
We report on a 5-year-old male, referred for initial genetic evaluation because of psychomotor delay and ASD. On clinical examination the boy presented with marked truncal obesity and mild dysmorphic features. The proband underwent several neurologic evaluations for his delay as well as for an episode of seizure, occurring in the context of a probable benign occipital epilepsy. At 9 years, he was reported to have severe anxiety and psychotic symptoms, notably auditory hallucinations, with poor response to risperidone.
Array-CGH analysis showed a maternally inherited 444 kb duplication of 8q11.23 encompassing RB1CC1 and FAM150.
Re-evaluation of the family history revealed possible psychiatric symptoms in his mother, as well as a maternal uncle suffering from chronic depression with psychotic episodes.
Our case demonstrates the phenotypic variability of duplications involving RB1CC1 and underscores the need to carefully assess the phenotype and relevant family history of such patients.

Investigation of a non-synonymous variant at ABCA13 in family with bipolar disorder

M. Almuallimi[1], *W. Corona*[2], *S. Detera-Wadleigh*[2], *F. J. McMahon*[2];
[1]*Georgetown University, Washington, DC, United States,* [2]*National Institute of Mental Health, Bethesda, MD, United States.*

Bipolar disorder (BD) is a major mental illness across all populations, with an estimated heritability of 80%, indicating a large genetic component. However, it is unclear how genetic variation such as rare single nucleotide variants (SNVs) contributes to the risk of the disease. Genome-wide association studies (GWAS) have shown support for the role of common genetic variation in increasing risk for bipolar disorder albeit, only modestly. Hence, the contribution of rare genetic variants that may exert a strong effect has been proposed. Complex diseases such as bipolar disorder are potentially caused by a combined effect of rare and common genetic alterations that would result in the disruption of gene networks. In this study, we investigated the effect of a potentially functional non-synonymous SNV (rs74859514) in the gene ABCA13 located in chromosome 7p21.3, which cause the amino acid substitution (Ala2223Pro) .This SNV was one of several uncommon functional variants shared by members of an extended family with BD who were exome-sequenced on Illumina arrays. Expression analysis using RT-qPCR was performed on patient-derived fibroblasts from two siblings carrying the mutation and diagnosed with BD. ABCA13 gene was found expressed in very low levels in fibroblasts as well as in other cell lines we tested previously, such as SH5Y5 and HeLa. We did not find significant differences in expression levels between heterozygous carriers of the ABCA13 variant when compared to a wild type fibroblast cell line. Sequencing of both genomic DNA (gDNA) and complementary DNA (cDNA) was performed to confirm each individual's genotype.

P06.35
Genetic association of RGS2 gene polymorphic locus with schizophrenia and typical antipsychotics response.

A. Gareeva[1], *D. Zakirov*[2], *E. Khusnutdinova*[2,1];
[1]*Institute of Biochemistry and Genetics of Ufa Scientific center of Russian academy of Sciences, Ufa, Russian Federation,* [2]*Bashkir State University, Ufa, Russian Federation.*

Several lines of evidence indicate that Regulator of G Protein Signaling 2 (RGS2) contributes to schizophrenia (SZ) vulnerability because it modulates signal transduction of neurotransmitter receptors that play a role in the pathogenesis of SZ. DNA samples of 258 patients with paranoid schizophrenia and of 263 healthy controls of Russian and Tatar ethnic group living in the Republic of Bashkortostan (RB) of Volga-Ural region of Russia were involved into the present study. All patients met the ICD10 criteria for SZ. Clinical response was determined by administering PANSS at base line and at days 21 and 45. The severity of extrapyramidal symptoms was assessed using The Simpson-Angus Scale (SAS). Genomic DNA was isolated from peripheral blood using the standard procedure. Differences between groups were tested by using unpaired t-test, analysis of variance (ANOVA), and chi-square test.
The present study is aimed at exploring whether rs2746071 of RGS2 gene could be associated with SZ and whether it could predict clinical outcomes in Russians and Tatars from RB.
In the result of the present study SZ high risk genetic markers RGS2*G/*G (rs2746071) in Russians (OR=4.08) and in Tatars (OR=4.88); allele RGS2*G in Russians (OR=2,37) and Tatars (OR=2,51), genetic markers of treatment efficacy in Tatars RGS2*G/*G (rs2746071) were obtained in individuals from the RB; considerable inter-ethnic diversity of genetic risk factors for this disease was revealed The results of this study support the hypothesis that RGS2 gene polymorphism contributes to interindividual variability in therapeutic effects and are involved in SZ pathway.

Schizophrenia is a mental disorder arising from a complex interaction of genetic and environmental factors. One of the strongest genetic risk factors is the 22q11 deletion and it has been suggested that genes located in this region might contribute to susceptibility to the disease. Our aim was to investigate the association between polymorphisms in *COMT*, *ZDHHC8, UFD1L* and *PRODH* genes, located at 22q11.2 region, with schizophrenia and treatment resistance schizophrenia (TRS). A total of 260 patients with schizophrenia was compared with 192 healthy controls. The patients were genotyped for rs4680, rs737865 and rs165599 for *COMT*, rs175174 for *ZDHHC8*, rs5746744, rs5992403 and rs1547931 for *UFD1L*, rs4819756, rs137852934, rs16983466, rs2238731, rs2904551, rs2904552, rs3970559, rs2238730, rs2870984, rs2870983, rs4550046 and rs372055 for *PRODH* polymorphisms using TaqMan® PCR assay, PCR-RFLP or sequencing. Chi-square test and logistic regression were used to verify Hardy-Weinberg equilibrium and to investigate the association of polymorphisms and disease or TRS respectively. All polymorphisms were in Hardy-Weinberg equilibrium except for *COMT* rs737865 in patient group. Significant associations were observed between schizophrenia and *PRODH* rs2904552 polymorphism (p=0.004, OR=2.52, 95%CI=1.33-4.76) and *COMT* rs737865 (p=0.034, OR=0.20, 95%CI=0.05-0.88). Higher *PRODH* GG frequencies and lower *COMT* CC frequencies were observed in patient group compared to control group. None polymorphism analyzed was associated with TRS. No functionality data of *COMT* rs737865 is available to this variant. *PRODH* rs2904552 is a functional polymorphism, which changes an aminoacid and modifies the protein structure, supporting an association between this gene and schizophrenia pathogenesis. Funding support: FAPESP 2011/50740-5, 2012/12669-0.

Association study of candidate gene polymorphisms with paranoid schizophrenia susceptibility in Russian population

D. Galaktionova[1], *A. Chudinov*[1], *V. Kuznetsova*[1], *A. Gareeva*[2], *E. Khusnutdinova*[2], *T. Nasedkina*[1];
[1]*Engelhardt Institute of Molecular Biology Russian Academy of Sciences, Moscow, Russian Federation,* [2]*Institute of Biochemistry and Genetics Russian Academy of Sciences, Ufa, Russian Federation.*

Schizophrenia is a common, chronic and complex psychiatric disorder, affecting 1.0% of the worldwide population. The data collected from family, twin, and adoption studies show unequivocally that schizophrenia is a predominantly genetic disorder with heritability ranged from 70-80%. Traditionally, genetic research of schizophrenia was focused on identifying linkage regions or on candidate genes and polymorphisms. Based on previous molecular genetic studies the following polymorphisms: CACNA1C (rs1006737), ANK3 (rs10761482), TPH1 (rs1800532), PLAA (rs7045881), SNAP25 (rs3746544, rs1051312), PLXNA2 (rs1327175) have been chosen and analyzed in 189 patients with paranoid schizophrenia and 195 healthy individuals. The genotyping procedure included multiplex PCR with fluorescently labeled nucleotides and allele-specific hybridization of labeled PCR products with a biochip. The statistically significant association between AA genotype of rs1800532 (TPH1) and risk of paranoid schizophrenia was found (p = 0.027). Also it was shown that C allele of rs1327175 (PLXNA2) was associated with family history in schizophrenic patients (p = 0.0001). The work was supported by Russian Foundation for Basic Research (grant #11-04-01998).

Gender specific epigenetic profiles in patients with schizophrenia

B. B. Rukova[1], *R. Staneva*[1], *S. Hadjidekova*[1], *V. Milanova*[2], *D. Toncheva*[1];
[1]*Department of Medical Genetics, Medical University, Sofia, Sofia, Bulgaria,* [2]*Department of Psychiatry, Medical University, Sofia, Sofia, Bulgaria.*

Background: Schizophrenia is one of the major psychiatric disorders in the world, characterized by severely debilitating behavioral abnormalities. Although it affects men and women equally, the illness has varying expression between the sexes. DNA methylation is a dynamic process that can be influenced by environmental factors. It is a major epigenetic modification that stably alters gene expression pattern in cells and is important for normal organismal development and cellular differentiation. This modification can be inherited through cell division. Materials and methods: We analyzed age-matched pools of 110 female, 110 male schizophrenia patients and corresponding healthy controls. We have performed high-resolution genome-wide methylation array analysis (Agilent 1x244K). We analyzed the methylation status of 27,627 CpG islands of all groups to identify methylation profile differences. Results: Our experiments show difference in the methylation profile between patients and controls. Comparing patients to healthy controls we established 69 differentially methylated genes (43 in female group and 26 in male group). Hypermethylated in the gene promoter region are 22 genes (13 in females and 9 in males). They play a role in neural system functioning (*PYGO2, GABBR1*), cell adhesion, cell division and signal transduction (*LRFN3, FXYD5, RMND5B u ARHGEF19*), transcription and translation (*FOXH1, ZNF488, EIF4E3, HEXIM1*) etc. Conclusions: Our data suggest that there is a major differences in methylation profile between males and females patients and controls. This dysregulation can play a critical role in schizophrenia etiopathogenesis. Acknowledgements: funded by project DMY 03-36/2011, Ministry of Education and Science.

Relationship between LSAMP gene and schizophrenia

K. Koido[1,2], *S. Janno*[3], *T. Traks*[1,2], *M. Parksepp*[3], *R. Balotsev*[3], *T. Eller*[3], *A. Must*[1,2], *S. Koks*[1,2], *J. Shlik*[4], *I. Toru*[3], *E. Maron*[3], *V. Vasar*[3], *E. Vasar*[1,2];
[1]*Department of Physiology, University of Tartu, Tartu, Estonia,* [2]*Centre of Excellence for Translational Medicine, University of Tartu, Tartu, Estonia,* [3]*Department of Psychiatry, University of Tartu, Tartu, Estonia,* [4]*Department of Psychiatry, University of Ottawa, Ottawa, ON, Canada.*

Schizophrenia is a devastating psychiatric syndrome with a median lifetime prevalence of 4.0 per 1000 and a lifetime morbid risk of 7.2 per 1000 persons and genetic heritability 80 %. It is now generally
accepted that the origins of the disorder lie early in neurodevelopment and that synaptic dysfunction and altered neural connectivity are likely to be important in its pathogenesis. The limbic system-associated membrane protein (LSAMP) is a 64-68-kDa glycoprotein that is found on the somata and dendrites of
neurons of cortical and subcortical regions comprising the adult mammalian limbic system, which is involved in the mediation of emotional behaviour, learning, and memory. We studied the relationship between single-nucleotide polymorphisms (SNPs) of LSAMP gene from chromosomal region 3q13.2-q21 and schizophrenia. The association study design was used: 22
SNPs covering the LSAMP gene were analyzed in 127
unrelated patients and in 171 healthy control subjects. All
subjects were individuals of Caucasian origin living in Estonia. The most common diagnose of patients was paranoid schizophrenia. The SNPlex Genotyping System and tetra-primer ARMS-PCR method were applied for genotyping, following association and haplotype
analyses with Haploview program. Association analysis revealed the most prominent associations with SNPs rs16824691 and rs9874470 (corrected allelic p values 0.0176 and 0.0033, respectively). Haplotype analysis revealed six haplotype blocks. Significant
haplotypic associations confirmed allelic associations. These results suggest that LSAMP gene from 3q13.2-q21 chromosomal region may possibly be related to schizophrenia.

P06.41

Transcriptomic profile of microRNAs and protein coding genes in peripheral blood of schizophrenia patients

V. Stoyanova[1], *T. Vachev*[1,2], *N. Popov*[1];
[1]*Medical University of Plovdiv, Plovdiv, Bulgaria,* [2]*University of Plovdiv „Paisii Hilendarski", Plovdiv, Bulgaria.*

MicroRNAs (miRNAs) are non-coding RNA molecules that are now thought to regulate the expression of many mRNAs. There is strong evidence that in schizophrenia inadequate or mistimed expression of a functional protein may occur due to post-transcriptional events such as abnormal miRNA regulation of a normal gene expression.
The present study aims to shade a light on the epigenetic aspect of schizophrenia pathophysiology. Therefore, we explore the dysregulation of miRNA expression levels and profile the transcriptom of protein coding genes of peripheral blood pooled samples from 30 schizophrenia patients and 25 healthy matched controls.
From microarray expression of 1898 miRNA in schizophrenia and control groups, 25 miRNAs were differentially expressed (p>0.05), where 15 are up-regulated and 10 down-regulated.
Performed digital gene expression tag profiling showed 1012 up-regulated and 2582 down-regulated genes. By qRT-PCR, 8 of the dysregulated miRNAs were tested and the analysis validated 7 of them (down-regulated hsa-mir-320c, hsa-mir-320a, hsa-mir-3173-5p, hsa-mir-421 and up-regulated mir-106a-5p, hsa-mir-192-5p and hsa-mir-222-3p).
Web based tool was used to assess potential miRNA-mRNA interactions. Among the predicted targets of dysregulated miRNAs, we discovered specific differentially expressed genes in periferal blood transcriptome, that were previously associated with schizophrenia (STAT3, BCL2L11, RAD9A, ERBB2, MYB and TFRC genes). Findings from this study strongly suggest that dysregulation of miRNA expression in periferal blood in patients with schizophrenia: 1) can contribute to the observed alterations in protein coding gene expression; 2) may lead to the pathophysiological conditions underlying schizophrenia; 3) provide an empirical source of non-invasive biomarkers for schizophrenia.

Sequencing of the 22q11.2 deletion in VeloCardioFacial syndrome to identify genetic variants predisposing to Schizophrenia

M. Guipponi[1], *F. Santoni*[2], ***C. Gehrig***[1], *X. Bonilla Bustillo*[2], *S. Dahoun*[1], *W. R. Kates*[3], *B. E. Morrow*[4], *S. Eliez*[2], *S. E. Antonarakis*[2];
[1]*Dpt of Genetic Medicine and Laboratory, University Hospitals of Geneva, Geneva 4, Switzerland,* [2]*Dpt of Genetic Medicine and Development, University of Geneva Medical School, Geneva 4, Switzerland,* [3]*Dpt of Psychiatry and Behavioral Sciences, State University of New York (SUNY) Upstate Medical University, Syracuse, NY, United States,* [4]*Dpt of Genetics, Albert Einstein College of Medicine, New York, NY, United States.*

Hemizygous deletions of a 3Mb region of chr22q11.2 region result in the Velo-cardio-facial syndrome (VCFS). The incidence of schizophrenia in VCFS

patients is 30x higher than in the general population making the del22q11.2 one of the most important risk factor for schizophrenia. The 22q11.2 deletion reduces the normal diploid to an haploid state and therefore can result in the unmasking of otherwise recessive alleles that may remain on the intact homolog. By sequencing the remaining copy of the chr22q11.2 in VCFS patients with and without psychosis/schizophrenia, we expect to identify variations in genes or functional elements that could increase the risk for this psychiatric phenotype.
We have selected 67 VCFS patients; 37 of them showed no psychiatric symptoms, and the rest (n=30) showed psychosis, schizoaffective disorder or schizophrenia. The whole 3Mb region on chr22q11.2 was captured and sequenced using Agilent and Illumina technologies, respectively. Genetic variants were called using an pipeline based on current best practices. The complete haplotype of the targeted 22q11.2 region was created for each subjects and compared between the two diagnostic groups. Two different loci showed a clustering of positive signals (pvalue < 0.001); a locus containing the TXNRD2, COMT and ARVCF genes which are involved in regulation of redox environment, degradation of catecholamine transmitters and adherens junction complexes, respectively and a locus containing the RTN4R gene which plays a role in axonal regeneration and plasticity. The sequencing of the remaining allele of microdeletion syndrome provides an excellent opportunity to identify risk variation for complex phenotypes.

Resequencing of *TBX1* Gene as a Candidate of Schizophrenia in Han Chinese Population

Y. Chuang[1], *M. Cheng*[1], *S. Hsu*[1], *H. Tsai*[1], *C. Chen*[2,3,4];
[1]*Yuli Veterans Hospital, Hualien, Taiwan,* [2]*Institute of Population Health Sciences, National Health Research Institutes, Chunan, Taiwan,* [3]*Chang Gung Memorial Hospital at Linkou and Chang Gung University School of Medicine, Taoyuan, Taiwan,* [4]*Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan.*

Recent studies substantiate a higher-than-expected frequency of schizophrenia in patients with 22q11.2 deletion syndrome (22q11DS), suggesting that chromosome 22q11.2 harbors the susceptible genes related to the pathophysiology of schizophrenia. TBX1 (T-box 1), a member of the T-box transcription factor family, is of particular interest for the identification of a family with a 23-bp frameshift deletion of *TBX1* and schizophrenia. We used the systemic mutation detection approach to identify any disruption or rare mutations in *TBX1* among 500 healthy controls and 500 non-22q11DS schizophrenic patients. A total of 39 genetic variants of the *TBX1* were identified in this study, including 16 known SNPs and 23 rare mutations. Six known SNPs in which minor allele frequencies were above 5 % were selected to analyze the association between the genotype and allele frequencies of these SNPs and schizophrenia. Twenty three rare variants including five missense variants were identified. Three missense mutations (p.Asp151Glu, p.Glu257Ala, p.Arg342Gln) were only detected in schizophrenic patients, and one (p.Asp155Asn) was only detected in control group. The mutation of p.Ala393Thr was found in both groups. There was no increasing burden of these missense mutations being found in the patient group (p= 0.4812). Missense mutations were examined by the amino acid analysis programs Polyphen-2 and SIFT to identify those predicted to be possibly or probably deleterious to protein function. Our study suggests some private genetic variations might occur in *TBX1* gene, and their relationship to the pathogenesis of schizophrenia needs further investigation.

Genome-wide copy number variant analysis in a large sample of suicide attempters

F. Degenhardt[1,2], *L. Priebe*[1,2], *J. Fischer*[1,2], *A. Hofmann*[1,2], *J. Strohmaier*[3], *M. Lang*[3], *S. Cichon*[1,4,5], *M. Rietschel*[3], *M. M. Nöthen*[1,2,6];
[1]*Institute of Human Genetics, Bonn, Germany,* [2]*Department of Genomics, Life and Brain Center, Bonn, Germany,* [3]*Department of Genetic Epidemiology in Psychiatry, Mannheim, Germany,* [4]*Division of Medical Genetics, University Hospital Basel and Department of Biomedicine, Basel, Switzerland,* [5]*Institute of Neuroscience and Medicine (INM-1), Research Center Juelich, Juelich, Germany,* [6]*German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany.*

Suicidal behaviour is influenced both by environmental and genetic factors. Based on twin studies, its heritability was estimated to be ~30%. A small number of potential suicide susceptibility genes have been identified. In order to unravel the underlying genetic architecture, additional studies are warranted. It is reasonable that these will include the analysis of copy number variants (CNVs). Rare CNVs have been identified as a risk factor for psychiatric disorders such as schizophrenia (SCZ).
Recently, the first CNV analysis in 189 patients with major depressive disorder (MDD) who attempted suicide was published (Perlis et al. 2012). The aim of our study was to further elucidate the potential role of CNVs as a risk factor for suicidal behaviour in a larger sample.
We used genome-wide SNP array data from: 1637 patients with SCZ (~27% attempted suicide), 882 patients with bipolar disorder (BPD;~35% attempted suicide), and 575 patients with MDD (~30% attempted suicide). All individuals were genotyped on HumanHap550v3, Human610-Quadv1, or Human660W-Quad arrays (Illumina, USA). CNVs were identified using QuantiSNP and PennCNV.
Two separate analyses were performed: genome-wide CNV analysis and CNV screening in genes reported by Perlis et al. (2012). The genome-wide CNV analysis is still ongoing and the results will be presented at the conference. In LOC339822 (Perlis et al.), duplications in five patients were detected. Three patients (two SCZ and one BPD) attempted suicide while one of the two affected MDD patients reported severe suicidal ideation. LOC339822 is in close proximity to SNTG2, a gene implicated in psychiatric disorders.

Effect of antipsychotics drugs in gene expression and promoter methylation of neurotransmisson genes in brain of Spontaneously Hypertensive Rats (SHR)

S. I. Belangero[1], *M. L. Santoro*[1], *V. K. Ota*[1], *P. N. O. Silva*[2], *R. S. Stilhano*[3], *C. M. Santos*[2], *M. C. Diana*[4], *A. Gadelha*[2], *L. M. N. Spindola*[1], *M. A. C. Smith*[5], *R. A. Bressan*[2], *S. W. Han*[3], *V. C. Abilio*[4];
[1]*São Paulo Federal University - Interdisciplinary Laboratory of Clinical Neurosciences / Department of Morphology and Genetics, Sao Paulo, Brazil,* [2]*São Paulo Federal University - Interdisciplinary Laboratory of Clinical Neurosciences / Psychiatry Department, Sao Paulo, Brazil,* [3]*São Paulo Federal University - CTCMol, Sao Paulo, Brazil,* [4]*São Paulo Federal University - Interdisciplinary Laboratory of Clinical Neurosciences, Sao Paulo, Brazil,* [5]*São Paulo Federal University - Department of Morphology and Genetics, Sao Paulo, Brazil.*

Recently our group suggested the SHR strain as an animal model to study schizophrenia aspects. Our aim was to verify treatment effect with antipsychotics drugs (APD) on the expression of 84 genes and the promoter region methylation of differentially expressed genes in the prefrontal cortex (PFC) and nucleus accumbens (NAC). Each group was composed of 8 rats treated 30 days with saline, risperidone, clozapine (CL) or haloperidol (HA). To expression analysis we used the PCRarray and t-test to investigate the significance, considering p≤0.001. Four genes were downregulated in PFC: Brs3 (CL: p=0.001; HA: p=0.0007), Drd2 and Drd3 in CL (p=0.001, p=0.0004) and Glra1 in HA (p=0.0008). Only Glra1 promoter showed hypermethylation in treated group (p=0.027). Drd2 and Drd3 downregulation demonstrate APD are playing a role in dopaminergic pathway of SHR. Brs3 is a bombesin neuropeptide receptor modulating pathways including dopaminergic. Studies found bombesin reduction in cerebrospinal fluid of schizophrenia patients and decreased social interaction in Brs3 knockdown mice. Our results suggest Brs3 dowrexpression may be correlated to elevated social interaction after APD, described previously in SHR. There is no study involving Glra1 and APD, however, the downregulation in expression and hypermethylation of promoter in the treated group suggest this drug can change the Glra1 expression by an epigenetic mechanism. In conclusion, our study indicated two genes related to APD action, pointed new pathways whereby APD may be acting and, that changes in the pattern of Glra1 expression could be modulated by hypermethylation of its promoter region. Financial Support: Fapesp 2010/0968-6.

Sleepwalking is a common childhood parasomnia that seldom persists into adulthood. Twin studies have shown higher concordance in monozygotic twins and relatives of sleepwalkers have a 10-fold increase in disease risk. A linkage study has suggested a candidate region on chromosome 20, but no responsible gene has been identified. We performed exome sequencing in an autosomal-dominant sleepwalking family. We sequenced two affected siblings and the unaffected mother using Agilent SureSelect All Exome Kit for enrichment and Illumina 100bp paired-end reads for sequencing. We generated on average 14.9Gb of sequence with 89% covered >= 20x. For candidate variant identification, we used an autosomal-dominant disease model and looked for heterozygous missense, nonsense, splice-site, stoploss and frameshift variants shared by the affected siblings. We excluded variants present in dbSNP135, the 1000genomes data, and an in-house exome database of unrelated phenotypes with a MAF > 1%. Subsequently, we excluded those variants shared by the two siblings but also found in the unaffected mother. This approach left 47 variants for co-segregation analysis in the pedigree. Of these 47 variants, 23 were compatible with the disease segregation pattern observed in the pedigree. The respective candidate genes include *C1R*, a component of the complement system, and *PZP*, which has been implicated in Alzheimer's disease. Sequencing of the variant-containing regions of the candidate genes in a cohort of 30 parasomnia cases detected neither the candidate nor additional variants in these genes. We are currently expanding the sleepwalking cohort in order to pinpoint the causal variant in the family.

Specific language impairment (SLI) and dyslexia are developmental disorders exhibiting deficits of spoken (SLI) or written (dyslexia) language in the absence of comorbid neurological deficits, despite adequate intelligence and education. Sex chromosome aneuploidies increase the risk of spoken or written language disorders but, compared to other developmental disorders, e.g. autism, individuals with SLI or dyslexia do not routinely undergo cytogenetic analysis.
To assess the frequency of sex chromosome aneuploidies within individuals with SLI or dyslexia, genome-wide single nucleotide polymorphism genotyping was performed in three sample sets: a clinical cohort of individuals with SLI referred to a child development centre (87 probands), a replication cohort of individuals with SLI, from both clinical and epidemiological samples (209 probands) and a set of individuals with dyslexia (310 probands).
In the clinical SLI cohort, three abnormal karyotypic results were identified in probands, representing a proband yield of 3.4%. In the SLI replication cohort six abnormalities were identified providing a consistent proband yield (2.9%). In the sample of individuals with dyslexia, two sex chromosome aberrations were found giving a lower proband yield of 0.6%. In total two XYY, four XXY (Klinefelter syndrome), three XXX, one XO (Turner syndrome) and one proposed XO/XY mosaic karyotype were identified.
The frequency of sex chromosome aneuploidies within each of the three cohorts was increased over the expected population frequency (approximately 0.1%) suggesting that genetic testing may prove worthwhile for individuals with language and literacy problems, enabling therapies associated with these sex chromosome abnormalities to be implemented more promptly.

P06.48

Identification of a genomic homozygous deletion of *ZNF277* in a child with SLI

F. Ceroni[1], *N. H. Simpson*[2], *C. Francks*[3,4], *G. Baird*[5], *G. Conti-Ramsden*[6], *A. E. O'Hare*[7], *E. Maestrini*[1], *E. Bacchelli*[1], *S. E. Fisher*[3,4], *D. F. Newbury*[2], *I. M.G.S.A.C*[1,2], *S. L. I. Consortium*[2];
[1]*Dipartimento di Farmacia e Biotecnologie, University of Bologna, Bologna, Italy,* [2]*Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom,* [3]*Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands,* [4]*Donders Institute for Brain, Cognition & Behaviour, Nijmegen, Netherlands,* [5]*Guy's & St Thomas NHS Foundation Trust, Newcomen Children's Neurosciences Centre, St Thomas' Hospital, London, United Kingdom,* [6]*School of Psychological Sciences, The University of Manchester, Manchester, United Kingdom,* [7]*Child Life and Health, University of Edinburgh, Edinburgh, United Kingdom.*

Specific language impairment (SLI) is a common neurodevelopmental disorder in which language abilities are below age expectations, in the absence of explanatory environmental or medical conditions, such as hearing loss, intellectual disability or autism. SLI affects 3-7% of English-speaking preschool children. During a genome-wide CNV scan using a multi-algorithm approach, we identified a homozygous deletion of 21,379bp in the *ZNF277* gene, overlapping exon 5, in an individual with severe receptive and expressive SLI. This deletion was of particular interest as it falls within the AUTS1 region of linkage to autism. *ZNF277* flanks the *DOCK4* and *IMMP2L* genes, which have been suggested to play a role in autistic spectrum disorders (ASD). We therefore screened cohorts of children with SLI or ASD and control subjects for the presence of *ZNF277* deletions. We observed an increased frequency of *ZNF277* deletions in probands with SLI (6/318, 1.9%) compared to both probands with ASD (1/253, 0.4%) and independent controls (2/224, 0.8%). We performed quantitative PCR analyses of the expression of *IMMP2L*, *DOCK4* and *ZNF277* in lymphoblastoid cell lines carrying either a *DOCK4* microdeletion or a *ZNF277* microdeletion. We found that, while *ZNF277* microdeletions affect the expression of *ZNF277*, they do not alter the levels of *DOCK4* or *IMMP2L* transcripts. Similarly, *DOCK4* microdeletions do not affect the expression levels of *ZNF277*. Given these findings, we postulate that *ZNF277* microdeletions may contribute to the risk of speech and language impairments in a manner that is independent of the autism risks previously described in this region.

P06.49

A balanced translocation t(3;9)(q25.1;q34.3) leading to *OLFM1* fusion transcripts in a patient with Tourette syndrome and comorbidity disorders

B. Bertelsen[1], *L. Melchior*[1], *L. R. Jensen*[2], *C. Groth*[3], *N. M. Debes*[4], *L. L. Skov*[3], *K. Brøndum-Nielsen*[1], *W. Chen*[5], *Z. Tümer*[1];
[1]*Applied Human Molecular Genetics, Kennedy Center, Copenhagen University Hospital, Rigshospitalet, Glostrup, Denmark,* [2]*Institute for Human Genetics, Ernst-Moritz-Arndt-University Greifswald, Greifswald, Germany,* [3]*Tourette Clinic, Herlev Hospital, Herlev, Denmark,* [4]*Næstved Hospital, Næstved, Denmark,* [5]*Max Delbrück Center for Molecular Medicine, Berlin Institute for Medical Systems Biology, Berlin, Germany.*

Karyotype analysis of a male with Tourette syndrome (TS), obsessive-compulsive-disorder and attention-deficit-hyperactivity-disorder revealed an apparently balanced and maternally inherited translocation, t(3;9)(q25.1;q34.3). The mother had tics, but no TS-diagnose. Using mate-pair sequencing we mapped the translocation breakpoints. The 9q breakpoint truncated the *OLFM1* gene, while the 3q breakpoint was within a region without known protein coding genes. However, *in silico* analyses revealed that this breakpoint truncated two
transcripts of unknown coding potential. Since translocations can unmask recessive mutations, sequencing of the *OLFM1* gene and the unknown transcripts was performed; however, no mutations were identified. Reverse transcription of RNA from blood of both individuals identified two fusion transcripts including the 5'-end of *OLFM1* and the 3'-end of either of the two

unknown transcripts, respectively. *In silico* analysis revealed open reading frames for both transcripts and resulting protein products predicted to encode a truncated OLFM1 protein lacking the olfactomedin domain.
Although widely expressed in neuronal tissues, the function of OLFM1 is relatively unknown. OLFM1 has not been directly associated with any neuropsychiatric disorders, but has been shown to interact with several proteins encoded by schizophrenia susceptibility genes. We therefore suggest that *OLFM1* could be involved in the TS/tic-symptoms of the patient and his mother, either through haploinsufficiency of *OLFM1* or presence of fusion transcripts/proteins. *OLFM1* expression levels will be measured in both individuals and *in situ* hybridization will be used to investigate whether the unknown transcripts show brain specific expression.

P07.01
R521C mutation in the FUS gene in a large Italian family

*R. Mazzei[1], R. Tortelli[2], A. Patitucci[1], A. Magariello[1], M. Muglia[1], R. Cortese[3], E. D'Errico[3], C. Ungaro[1], G. Logroscino[2], I. L. Simone[2], **F. L. Conforti**[1];*
[1]Institute of Neurological Sciences, Mangone (CS), Italy, [2]Department of Neurosciences and Sense Organs -Università, Bari, Italy, [3]Department of Neurosciences and Sense Organs-Università, Bari, Italy.

FUS/TLS gene mutations were identified in familial and sporadic amyotrophic lateral sclerosis (ALS). Genotype-phenotype correlation for this gene is mostly characterized by early age at onset, high rate of progression, early involvement of neck and axial muscles and predominant lower motor neuron involvement, but a high variability has been described.
We studied a four-generation family in which eight individuals of both sexes were affected by motor neuron disease. The pedigree showed a dominant pattern of inheritance. Neurological examination was performed and these patients were clinically diagnosed as ALS. We performed mutational analysis of FUS exons 5, 6, 12, 14 and 15 in the proband, resulted negative for mutation in *SOD1, ANG, VAPB* and *TARDBP* genes, identifying the known heterozygous missense mutation c.1561C>T (p.R521C) in exon 15. Further analysis demonstrated the same mutation in the DNAs from the proband's affected mother and the paucisymptomatic aunt, confirming segregation of the mutation with disease in this family.
R521C is the most common dominant missense mutation in familial ALS related to FUS gene. However this is the first report of a large four-generation Italian ALS family with this mutation. The genotype-phenotype correlation in this family confirmed that the expression of FUS R521C mutation extends beyond classical ALS. Early involvement of neck and proximal limb muscles and a predominant LMN phenotype were confirmed as typical features, but the phenotypic expression may be characterized by a high variability in terms of age at onset and site of onset of the disease also within the same family.

P07.02
Mitochondrial network genes in skeletal muscle of amyotrophic lateral sclerosis patients

*W. Lattanzi[1], F. Censi[2], G. Calcagnini[2], A. Giuliani[3], M. Barba[1], M. Sabatelli[4], E. Ricci[4], F. Michetti[1], **C. Bernardini**[1];*
[1]Insitute of Anatomy and Cell Biology, Università Cattolica S. Cuore, Rome, Italy, Rome, Italy, [2]Istituto Superiore di Sanità, Department of Technologies and Health, Rome, Italy, [3]Istituto Superiore di Sanità, Department of Environment and Health, Rome, Italy, [4]Institute of Neurology, Università Cattolica S. Cuore, Rome, Italy, Rome, Italy.

Recent evidences suggested that muscle degeneration might lead and/or contribute to neurodegeneration and play a key role in the etiopathogenesis and progression of amyotrophic lateral sclerosis (ALS) (Dobrowolny et al, J Cell Biol 2005; Wong et al Hum Mol Genet 2010). To test this hypothesis, this study attempted to categorize the functionally relevant genes within the genome-wide expression profile in the skeletal muscle of ALS patients, using microarray technology and gene regulatory network analysis. The correlation network structures significantly change between patients and controls, indicating an increased inter-gene connection in patients compared to controls.
Looking at the biological functions of the strongly connected genes of the ALS patients, a large number of mitochondrial genes belonging to the oxidative phosphorylation pathway were represented.
On the whole the perturbation of gene expression occurring in the muscle of affected individuals involves genes that share relevant functional connections. The network observed in the ALS muscles includes genes (PRKR1A, FOXO1, TRIM32, ACTN3, among others), whose functions connect the sarcomere integrity to mitochondrial oxidative metabolism. In particular connection between PRKAR1A, FOXO1 and the ubiquitin ligase TRIM32 provide some hints towards the delineation of the molecular events associated to human muscle atrophy.
In conclusion, the results obtained in this study, supported by some of the most recent literature data, could pave the way to future targeted studies focusing on the functional link between genes involved in metabolic pathways and muscle contractility.

P07.03
Deletion of UBE3A gene in brothers with Angelman syndrome close to breakpoint of inversion at 15q11.2 and 15q26.1

***Y. Kuroda**[1], I. Ohashi[1], T. Naruto[1], K. Ida[1], T. Wada[2], K. Kurosawa[1];*
[1]Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan, [2]Division of Neurology, Kanagawa Children's Medical Center, Yokohama, Japan.

Angelman syndrome (AS) is characterized by severe intellectual disability with major speech impairment, ataxia and behavioral uniqueness. The underlining molecular deficit is the failure of maternal copy of the imprinted UBE3A gene due to maternal deletions, the most common present in 70-75% of case, which is detected by FISH of the UBE3A region. Only a small number of intragenic or whole genomic microdeletions of UBE3A have been reported. We report on two brothers with AS with microdeletion of 15q11.2-q12 emcompassing UBE3A gene, close to breakpoint of inversion at 15q11.2 and 15q26.1. The brothers were the first and second children of unrelated and healthy parents. They were born at term after uneventful pregnancy. Patient 1 (older brother) had developmental delay, walked with ataxic gait, and did not speak word at 6 years old. He developed seizure at 4 years-old. Patient 2 (younger brother) had also developmental delay and started sitting at 15 months. They had mild phenotype and behavior of AS. Karyotype revealed pericentric inversion of 15q and FISH test revealed deletion of UBE3A region. Array CGH revealed 467kb deletion at 15q11.2-q12, only emcompassing UBE3A and a part of SNORD115, and 53kb deletion at 15q26.1. Their mother revealed normal karyoptype and no deletion of 15q11.2-q12 with array CGH, so we assumed germline mosaicism. This report is a rare familial case with AS detected by routine FISH test. We suggest that array CGH can detect atypical submicroscopic deletion of UBE3A in patients with mild AS phenotype.

P07.04
Altered splicing of the BIN1 muscle-specific exon in human and dogs with highly progressive centronuclear myopathies

***J. Böhm**[1], N. Vasli[1], M. Maurer[2], D. Shelton[3], U. Schara[4], T. J. Anderson[5], J. Weis[6], L. Tiret[2], J. Laporte[1];*
[1]IGBMC, Strasbourg, France, [2]ENVA, Maisons-Alfort, France, [3]University of California, San Diego, CA, United States, [4]University of Essen, Essen, Germany, [5]University of Glasgow Veterinary School, Glasgow, United Kingdom, [6]RWTH, Aachen, Germany.

We have identified a splice mutation of the muscle-specific exon 11 of BIN1 as the genetic cause of the Inherited Myopathy of Great Danes (IMGD). This severe canine muscle disorder typically starts before 10 months of age with severe debilitating muscle weakness. BIN1 codes for amphiphysin 2, a key factor in muscular membrane remodeling implicated in excitation-contraction coupling (ECC). The muscle-specific exon 11 codes for a phosphoinositide-binding domain, which is essential for the membrane-deforming properties of amphiphysin 2. In humans, BIN1 mutations have been associated with centronuclear myopathy, showing an abnormal internalization of nuclei on muscle biopsies. All mutations were found in the ubiquitous exons and together with the IMGD model we present the first mutation in humans affecting the muscle-specific exon 11. Both human and canine mutations have a strong impact on the splicing of exon 11 and patients and dogs have a very similar etiopathology. Comparative histological and ultrastructural analyses demonstrated striking similarities between the human and the canine conditions and immunolabeling revealed a defective structure of the triad, harboring the ECC machinery. Myotubes transfected with the exon 11 containing isoform showed massive tubulation, whereas the construct

without exon 11 did not have this effect. Our data suggest that the amphiphysin 2 muscle isoform plays an important role in triad buildup and/or maintenance and that defective excitation-contraction coupling is a primary cause of the progressive human and dog diseases. The identification and characterization of a spontaneous canine model represents a faithful model for preclinical trials of potential therapies.

Progressive cerebello-cerebral atrophy is an extremely rare entity described in 2003 in less than 10 patients (Ben-Zeev *et al.*). Clinical findings consist of severe spasticity, profound mental retardation with progressive microcephaly. Brain imaging shows progressive cerebellar atrophy followed by severe cerebral atrophy. The disease is caused by mutations in the *SEPSECS* gene. The Sepsecs protein needs a cofactor, pyridoxal phosphate (PLP), and is involved in the syntheses of Selenocysteine, an essential component of the active sites of some enzymes (selenoenzymes). We describe a family with 2 affected children. Patient A is the 2nd child of non-consanguineous parents. The boy was born with normal parameters, after an uneventful pregnancy. Bilateral adductus thumb were noticed at birth and generalized stiffness appeared rapidly with tetra spastic paraplegia. He developed with a profound mental retardation. His best milestones were smiling at 4,5 months and head control at 24 months. Spontaneous movements were very poor. He developed severe postnatal microcephaly (-3SD at 6 months and -7SD at 7 years). Successive brain MRI found progressive cerebellar atrophy, rapidly followed by severe cerebral atrophy. Patient B is the 4th child of the family. Recurrence of the disease was suspected in the young sister of patient A because she displayed dystonic movements, stiffness of the trunk at 3 months and progressive microcephaly. *SEPSECS* sequencing revealed in the affected children, 2 novel mutations: a splice mutation predicted to affect splicing of exon 1, and a missense predicted to disrupt folding of the protein or affect binding with PLP.

Recently, *COL4A1* mutations have been reported in porencephaly and other cerebral vascular diseases, often associated with ocular, renal and muscular features. In this study, we aimed to clarify phenotypic spectrum and incidence of *COL4A1* mutations.
We screened for *COL4A1* mutations in 61 patients with porencephaly and 10 patients with schizencephaly, which may be similarly caused by disturbed vascular supply leading to cerebral degeneration, but can be distinguished depending on time of insult.
COL4A1 mutations were identified in 15 patients (21%, 10 mutations in porencephaly and 5 mutations in schizencephaly), who showed a variety of associated findings including intracranial calcification, focal cortical dysplasia, pontocerebellar atrophy, ocular abnormalities, myopathy, hyper-CK-nemia, and hemolytic anemia. Mutations include 10 missense, a nonsense, a frameshift, and three splice site mutations. Five mutations were confirmed as de novo events. One mutation was co-segregated with familial porencephaly, and two mutations were inherited from asymptomatic parents. Aberrant splicing was demonstrated by reverse transcriptase PCR analyses in two patients with splice site mutations.
Our study first confirmed that *COL4A1* mutations are associated with schizencephaly and hemolytic anemia. Based on the fact that COL4A1 mutations were frequent in patients with porencephaly and schizencephaly, genetic testing for *COL4A1* should be considered for children with these conditions.

P07.07

A novel mutation in the FRMD7 gene in an Iranian pedigree exhibiting congenital Nystagmus: A case report

m. noruzinia[1], *M. Garshasbi*[1], *G. M. Bahrami*[1], *R. Weissmann*[2], *Y. Shafeghati*[3], *A. W. Kuss*[2];
[1]*Department of Medical Genetics; Faculty of Medical Sciences; Tarbiat Modares University; Tehran, Iran, tehran, Islamic Republic of Iran,* [2]*Department of Human Genetics, Interfaculty Institute of Genetics and Functional Genomics, Ernst Moritz Arndt University, 17475, Greifswald, Germany,* [3]*Department of medical genetics, Sarem Women Hospital, tehran, Islamic Republic of Iran.*

Congenital nystagmus is a genetically heterogeneous disorder characterized by repetitive, involuntary, to and for oscillation of the eyes, which may be inherited with the pattern of X-linked, Autosomal dominant and rarely Autosomal recessive. To date, three X-linked types of congenital nystagmus (NYS1, 5 and 6) have been introduced, which the most prevalent form (NYS1) results from mutations in the FERM domain-containing-7 gene (FRMD7). Here, we report a large 5-generation Iranian pedigree consistent with the pattern of recessive inheritance. Twelve individuals in the pedigree were suffering from congenital nystagmus and all of them presented involuntary, pendular movement of the eyes, and decreased visual acuity without any neurologic abnormalities. STR markers' analysis did not show any linkage with known autosomal recessive gene. Due to large locus heterogeneity and absence of net inheritance pattern in this family, we performed exome sequencing to elucidate the pathogenic mutation.
A novel truncating mutation (Q13X) in exon 1 of FRMD7 was detected in the proband, which was confirmed by direct sequencing. This mutation co-segregated with the disease in the family and we could not find this mutation in 100 chromosomes from ethnically matched healthy controls by restriction fragment length polymorphism (RFLP) technique.

Congenital myasthenic syndromes (CMS) are clinically and genetically heterogeneous disorders characterized by a neuromuscular transmission defect. In recent years, causative mutations have been identified in at least 15 genes encoding proteins of the neuromuscular junction. Mutations in MUSK are known as a very rare genetic cause of CMS and have been described in only 3 families, world-wide. Consequently, the knowledge about efficient drug therapy is very limited. We identified a novel missense mutation (p.Asp38Glu)
